In line-at-a-time addressing, the time available to activate each line is the frame time divided by the number of display lines. The frame time is the total time available to address the entire display array, usually ca. 16.6 ms (60 Hz) for flicker-free images. In refreshed displays, the activation of the picture element and the persistence of the electro-optic effect make up the actual time that a display effect is visible. If a very large number of lines is to be scanned during frame time, the entire performance is degraded because insufficient time is left for proper activation.

In display configurations in which the display material exhibits inherent memory, these problems do not occur. The images formed by the picture elements can be sustained without refreshing until another image is desired. Memory can also be introduced artificially by a proper circuit for each picture element (extrinsic or active matrix addressing; see Section 4.2.4).

4.1. Light-Generating (Active) Displays

Flat panel light-generating displays make information visible by emission of light as a result of picture element activation. Important is the *light output conversion efficiency*, i.e., the ratio of photon output power, $P_{\mathrm{out}} = h\nu \cdot p/t$, to electrical input power, $P_{\mathrm{in}} = e\,V \cdot n/t$ ($h\nu$ is the energy per photon, p/t is the number of photons generated per unit time t, n/t is the number of inflowing electrons per unit time, and eV is the average electron energy before photon emission).

The ratio

$$\eta = P_{\mathrm{out}}/P_{\mathrm{in}} = (h\nu/eV)\cdot p/n = \eta_{\mathrm{E}} \cdot \eta_{\mathrm{n}}$$

can be factored into the photon – electron energy ratio η_{E} and the photon – electron conversion efficiency ratio η_{n}. The former is close to unity in most light-emitting displays. Even in high electron energy devices like the CRT, down conversion of electron energy occurs in the phosphor through creation of secondary electrons with energies comparable to the photon energy before the onset of light emission. However, η_{n} is one or two orders of magnitude below unity, which is why active displays always require more power than ambient-light-modulating displays.

4.1.1. Gas Discharge

Gas discharge is the fundamental phenomenon for all types of plasma displays, and in this sense these displays are similar in operation to the familiar neon lamp. The displays consist of two plates of glass enclosing a gas-filled volume. The gas mixture usually consists of chemically unreactive noble gases like neon plus 3 – 8 % xenon with traces of argon or helium at a pressure of about 7 kPa. In matrix displays both glass plates carry electrode strips oriented orthogonally to each other. When the electrodes are activated a discharge is created and the xenon atoms – excited by energetic electrons – begin to radiate ultraviolet light which can be transformed into visible light by appropriate photoluminescent phosphors.

Figure 6. Schematic current – voltage ($I - V$) characteristic of a gas discharge

Figure 6 schematically shows the logarithmic current – voltage ($I - V$) characteristic of a typical gas discharge. In such a reaction numerous different ionization and excitation processes occur. The most important one is the ionization of neutral atoms by electrons, resulting in a positively charged ion and an additional free electron. The ions flow to the cathode and induce secondary electron emission there, which in turn leads to new avalanches and the growth of the discharge current. Depending on the voltage across the gas the feedback loop of the process described can be greater than unity, and without any external resistance the current would grow unrestricted. This strong nonlinearity is one of the major advantages of a gas discharge, allowing practically unlimited multiplexing without any additional nonlinear devices.

Figure 7. Characteristic luminous regions of a gas discharge

The principal luminous regions of a gas discharge are shown in Figure 7. The positive column discharge is used in fluorescent lamps for room lighting and in neon signs for commercial advertising. In plasma displays, however, the reduction of the electrode separation shortens the available portion of the positive column, while the negative glow length is maintained. In commercially available a.c.-addressed plasma displays the negative glow dominates in light generation over the positive column. Unfortunately, the negative glow is a much less efficient light generator than the positive column. Designs that make better use of the positive column would help to increase the luminous efficiency [21].

4.1.1.1. Alternating-Current Plasma Displays

Today the technically and commercially most successful plasma displays are color a.c. plasma panels. Their fundamental structure is shown in Figure 8 A together with a cross-sectional view in Figure 8 B. The devices consist of glass back and front plates.

The back plate carries the silver x-axis address electrodes; a 20 µm-thick layer of dielectric glass; screen-printed, sandblasted, or photocast barrier ribs of about 150 µm in height between the address electrodes, which suppress optical cross-talk between neighboring discharge cells; and phosphors that emit red, green, or blue light on UV excitation. In color plasma displays the xenon component of the gas mixture emits UV light in the 147 nm range. In a line-at-a-time scanned matrix display the overall brightness decreases with increasing number of scanned lines, and therefore the inherent memory function is extremely valuable. RGB light emission is achieved by the photoluminescence of phosphors excited by the ultraviolet light. Typical phosphors for plasma displays are $(Y,Gd)BO_3:Tb^{3+}$ for red, $ZnSiO_4:Mn^{2+}$ for green, and $BaMgAl_{10}O_{17}:Eu^{2+}$ for blue emission.

The front glass plate is equipped with two transparent parallel electrodes, the sustain and scan electrodes, which are covered by a thick-film dielectric The inner surface of this dielectric layer, which is in contact with the noble gas, is given a special 0.5 µm-thick coating of MgO. This coating ensures longer display life by preventing ions from bombarding the dielectrics. It also has a low threshold for secondary electron emission, thereby allowing for lower operating voltages.

The insulating dielectric layers have two basic functions. First, they limit the current (and thus prevent arcing) by coupling the electrodes capacitively to the gas discharge, and second they help to achieve memory function by forming a capacitor in series with each pixel.

The establishment of a discharge during one cycle induces charge on the capacitance formed by the dielectrics with a field direction opposite to the polarity of the applied potential. These wall charges add to the applied voltage when the voltage polarity is reversed in the next cy-

Figure 8. A) Fundamental structure of an a.c.-addressed plasma display (Fujitsu); B) Cross section of a (green) subpixel discharge cell in such displays

cle and thus allow breakdown at a lower applied potential. The discharge current and the resulting light occur in short pulses. At typical operating frequencies of 50 or 60 kHz, the cumulative effect of many pulses results in typical luminance values between 300 and 600 cd/m^2. The stored charge permits display memory. The entire matrix array is supplied with a repetitive pulse voltage, the *sustain voltage*, below that required to start the discharge. An additional pulse across a selected picture element in the matrix starts the discharge at this picture element, and the discharge sequence is sustained by repeated pulses with the aid of the charge stored in the series capacitance. The local discharge is extinguished when the stored charge is reduced by one smaller *erase pulse*, which makes the field across the capacitance too low for firing.

Figure 9 Shows the voltage waveforms for addressing plasma display pixels as described above.

4.1.1.2. Plasma Display Addressing

The fundamental method for addressing practically all presently available a.c. plasma displays is called address display separation (ADS). With

Figure 9. Voltage waveforms for addressing plasma display pixels

this method an a.c. sustain voltage is applied to all the cells of a line. To write the cells an additional pulse is applied to all cells during the address period. Those cells which have to stay Off receive a corresponding column pulse that cancels the effect of the write pulse. The obtained distribution is maintained for the required sustain period by the sustain signal until a special erasing signal quenches the discharge for all pixels. This signal is often called "setup" or "reset". This signal has two important purposes. First, it causes some minimal level of discharge activity that primes the next gas discharge. Priming is important in plasma displays since it provides a controlled low level of ionization necessary to achieve reliable starting conditions for the discharge. The other important function of the setup pulse is to place the Off-state wall voltage to a precise and reproducible level that will allow the "write" operation to occur reliably [21]. After erasure, all cells of the line are in Off state waiting for a new writing process.

To achieve gray scale with binary plasma displays, the setup – address – sustain sequence is used in a multiple-subfield arrangement, as shown in Figure 10. In this example the image frame time is divided into eight subframes, each weighted with a binary power multiple of the smallest time. Each of them has a setup and address period of equal length. In each subframe the entire screen image is addressed, selectively and sequentially one line at a time from top to bottom. This writes an image into the plasma display's inherent memory. Then a sustaining cycle is executed which produces light from those pixels which were written in the On state. The eight bits of gray-scale code for each pixel determines which subframes must be turned on for that pixel during the image frame time. This scheme works well for still images, but has to be modified for motion pictures due to visible artefacts.

4.1.1.3. Remaining Problems for Plasma Displays

There are essentially three major issues still to be solved. One is *phosphor degradation*. The materials used are basically those developed by the flourescent lamp industry. Of these, the blue-emitting material has the shortest life, while the red material is very stable. Most manufacturers quote a lifetime of plasma displays to half luminance to be between 10 000 and 30 000 h. The mechanism of phosphor degradation is not well understood, but a doubling of the lifetime is desirable.

The current *manufacturing cost* of plasma panels excludes its use as a mass consumer product. A large proportion of the manufacturing cost is determined by material cost [22], with an important contribution from electronic drivers. However costs can be cut by using cheaper glass, by further improvement in the driver area by using silicon-on-insulator technologies, and advanced functional integration, which may lead to the production of a complete 42-inch RGB module for about $ 1000.

Probably the greatest challenge for plasma display engineers is to *increase the efficiency* of the devices. Most plasma displays today operate at a luminous efficiency of about 1 lm/W. There is considerable effort in academia and industry to find ways to improve the efficiency. Flourescent lamps show efficiencies around 80 lm/W, and the target for plasma displays has been set at 5 lm/W for the near future. To achieve this goal improvements in the discharge efficiency,

Figure 10. Address display separation (ADS) technique for gray scale

better optical coupling, and higher phosphor efficiencies have to be attained.

4.1.2. Cathodoluminescence

In the last fifty years several suggestions have been made for making *flat CRTs* with ingenious deflection plates, multiple electron beams, decoupling of electron beam selection and high-voltage acceleration or the provision of large-area screen-sized cathodes, whereby the electrons could be extracted through the aperture holes of a matrix-addressed grid separating cathode and screen. None of these many attempts made great inroads in computing or entertainment applications. The only cathodolominescent flat panel devices with significant sales are vacuum flourescence displays. They are briefly discussed below together with field-emission display technology, which some companies believe to be the ultimate solution for the flat CRT problem.

4.1.2.1. Vacuum Fluorescence Displays (VFDs)

Vacuum fluorescence displays (VFDs) based on low-voltage cathodoluminescence were developed in Japan in the 1960s and are still being manufactured, mainly in that country. The technology is well suited for low-information devices, like bar graphs and numerics, but is also capable of alphanumerics and low-resolution video display.

The simple numeric device consists of an oxide-coated heated emitter filament and seven anodes in a figure-of-eight configuration mounted in a flat evacuated glass tube (Fig. 11). The anodes are covered with the low-voltage phosphor ZnO:Zn, which gives a bluish green luminance when bombarded with ca. 20-eV electrons. The efficiency is 5 – 10 lm/W. The thin filament is located in front of the anodes. The anode construction is shown in Figure 11 C. The filament is kept below the temperature that leads to visible thermal emission and therefore is barely visible. By raising the potential at the selected anode segments to + 15 V relative to the cathode, any required numeral can be displayed. This is improved by introducing a grid between anodes and cathode, allowing several digits to be multiplexed. In this approach, the corresponding anode segments are interconnected and the digit position is selected by the grid potential. Only the digit that receives both anode and cathode grid signals produces light.

These displays are normally viewed from the back, i.e., through the grid. Transparent anode connectors and thin phosphor layers enable the construction of VFDs that are viewed from the front, thus allowing for a larger viewing angle.

The grid-controlled flat multidigit packages had a significant impact on the market for digital clocks, hand-held calculators, and numeric indication in audio and video equipment. Power dissipation is quite low. A nine-digit tube giving 600 cd/m^2 requires a total of ca. 40 mW.

The incorporation of colors other than blue-green requires new low-resistivity phosphors. A number of phosphor mixtures have been tried,

Figure 11. Vacuum fluorescence displays: (a) exploded view of a seven segment numeric display (b) cross section of the same device (c) details of the anode structure

but none matches the efficiency of ZnO:Zn. Nevertheless, VFDs with green-blue, yellow, and orange emission are available.

4.1.2.2. Field-Emission Displays (FEDs)

The operating principle of these vacuum electron devices is comparable to vacuum fluorescent displays with the important difference that the electrons are not emitted by thermal activation from hot filaments but rather by field emission from a cold cathode. Electrons escaping from the cathode by quantum-mechanical tunnelling are accelerated towards a phosphor screen, where their energy is partly transformed into light (Figure 12). Many FEDs use microscopic tips for which the field is determined by the microscopic tip geometry and the voltage difference between the cathode and closely positioned gates. The statistical probability that electrons in the metal tip will tunnel through the metal – vacuum barrier is given by the Fowler – Nordheim tunneling equation for field emission. This equation relates the emission current density with the applied electrical field, the work function of the emission surface and its geometry.

Field enhancement induced by tips is the most widely investigated method to obtain useful currents at moderate macroscopic fields. One way of fabricating microtips is to make use of the wet-etching properties of *n*-type silicon. [23] Meyer developed a fabrication process for molybdenum microtip cathodes on glass. The process also provides a gate electrode with a 1.4 μm self-aligned hole around each cathode tip. This original design was refined through the addition of a ballast resistive layer to average out random fluctuations of current yield between tips. The negative electron affinity on diamond-like carbon surfaces has fuelled research in diamond emitters as a low-cost manufacturing alternative. A more recent version of a field emitter was introduced by Canon and is based on the creation of nanometer-wide cracks in thin-film palladium oxide containing nanocrystalline particles. When a potential is applied across the small gap, electrons tunnel across, and some of them are inelastically scattered at the positive edges of the gap, from where they are attracted to the positive anode. An overview on field emitters is given in [24].

Figure 12. Basic structure of a field emission display

4.1.3. Electroluminescence

The term *luminescence* generally describes the generation of light not caused solely by a heated black body radiator. *Electroluminescence* denotes light emission phenomena related to the action of electric fields in crystalline or organic solids. Due to the fundamentally different physical mechanisms, a distinction is made between light generation due to low or high electric fields. The former case refers to the emission that occurs after the injection of minority carriers across the forward-biased *p-n* junction and the subsequent radiative recombination of electrons and holes in single-crystal semiconductor diodes or equivalent structures made of organic material. The latter is related to the emission of light in polycrystalline material exposed to high electrical fields, where generation of hot electrons and impact excitation of activators (dopants) become possible.

The term *light-emitting diode* (LED) originally was used for displays made of inorganic single-crystal semiconductors. With the recent advent of recombination radiation from organic materials, the family of light emitting diodes was enlarged to include (small molecule) organic material based OLEDs and similar devices based on organic polymers material, often called PLEDs.

The expression *electroluminescent display* (ELD, sometimes also called high-field electroluminescent display or thin film electroluminescent (TFEL) display, is generally reserved for displays made of thin film polycrystalline phosphors or of powder phosphor material in a binder.

4.1.3.1. Visible Light Emitting Diodes (LEDs)

In forward biased *p-n* junction LEDs the emission resulting from radiative recombination of electrons and holes has a wavelength corresponding to the band gap of the material used.

The efficiency of conversion of the electrical energy input to the LED into the desired light emission depends on three factors:

1) The excitation of excess minority carriers. At a *p-n* junction passing $10\,\mathrm{A/cm^2}$ minority carriers are injected at a rate of about 10^{24} carriers/cm^3 within a narrow region of $1-2\,\mu\mathrm{m}$. Assuming a lifetime of 10^{-9} s this generation yields a net surplus of 10^{15} carriers/cm^3, much above the typical equilibrium minority carrier concentration.

2) Radiative recombination of these carriers to the ground state can occur via many pathways. Some are radiative, others are not, depending on material properties such as band structure, defects, and dopant nature and concentration. Radiative transitions can occur from the conduction band to the valence band (with the emitted photon energy corresponding to the gap between the two) or via intermediate impurity levels.
3) Extraction of the generated light from the volume of the material to the surroundings. Since the materials in which the recombination radiation is generated usually have high indices of refraction much of the light cannot leave the volume of the material due to total reflection and eventual internal absorption. One way of improving the situation is to produce a micro-roughness on the semiconductor surfaces.

Visible LEDs have been on the market since the 1960s. However, only in the last few years have high-performance LEDs become available in all colors, allowing the fabrication of full-color flat panel displays viewable in direct sunlight. Before 1985, when LED performance was generally in the range of less than 2 lm/W, LEDs were mostly limited to indicator-type applications. Since 1985 the perfomance has increased to as high as 50 lm/W for the highest performance type of red-emitting AlInGaP LEDs. With the development of GaInN devices, the range of colors has expanded to include violet, blue, and pure green, so that high-performance LEDs are available throughout the color spectrum. With an efficiency that exceeds many types of conventional lighting sources, LEDs can now be used in a variety of new application areas such as vehicle lighting, traffic signals, road signs, and large-area displays for advertisment. Red-emitting high-performance devices based on AlGaAs technology were first introduced to the market around 1983. In 1991 red, orange, yellow, and green LEDS based on AlInGaP appeared [25], [26]. In 1993 this was followed by the succesful commercialization of a new materials system for the green and blue part of the visible spectrum: the InGaN system [27].

The external quantum efficiency versus emission wavelength for LEDs is shown in Figure 13

Figure 13. External quantum efficiency of commercial light emitting diodes plotted versus their peak emission wavelength

The AlInGaP system shows the highest performance in the red and amber region, but the efficiency degrades sharply towards the green region. Nevertheless, green AlInGaP LEDs can be produced with an efficiency still doubling that of the conventional GaP:N green devices. The wavelength, however, being 570 nm or greater is perceived as a yellowish green and therefore is not suitable for many full-color applications. The efficiency degradation towards green is due to the fundamental transition in the band structure of the semiconductor alloy, which changes from direct-type to indirect type with much lower light-generating efficiency. The direct to indirect change is also the reason why AlGaAs LEDs work well in the infrared and red but not in the green part of the spectrum. The InGaN system is a direct-type semiconductor all the way from the red to the ultraviolet. The best devices have been made in the blue and green regions. In the yellow there is a sharp fall off due to problems with materials growth and a bad match in atomic spacing between the different layers of the device structure.

Table 2 shows a selection of commercially available LEDs and their characteristics (data taken from [69]), Figure 14 illustrates their chromaticity in the C.I.E. diagram.

Table 2. Comparison of red, geen, and blue LEDs

Material	Colour	Chromaticity		Peak wavelength,	Half-width,	External quantum efficiency,	Luminous efficiency
		x	y	nm	nm	%	lm/mW
InGaN	ultraviolet			370	11	3	-
InGaN	blue	0.13	0.08	465	30	11	7
InGaN	blue-green	0.18	0.40	495	35	10	18
InGaN	green	0.10	0.55	505	35	10	25
InGaN	green	0.17	0.70	520	40	8	25
GaP:N	yellow-green	0.45	0.55	565	30	0.4	2.4
AlInGaP	amber	0.57	0.43	590	15	5	20

∗ Incandescent. ∗∗ Fluorescent.

Figure 14. Chromaticity diagram for red, green, and blue semiconductor LEDs

With the availability of efficient blue and even UV LEDs the application of LEDs and phosphors for illumination purposes has gained momentum. Three methods for obtaining white light from LEDs are being followed. The first is to combine three individual blue, green, and red LEDs and the second is a binary complementary system of blue and yellow or blue-green and amber emissions, based on InGaN, GaP, and AlInGaP. The third method involves blue- or UV-emitting $In_xGa_{1-x}N$ and corresponding RGB phosphors or blue-emitting $In_xGa_{1-x}N$ LEDs and YAG:Ce^{3+} phosphor.

4.1.3.2. Organic and Polymer Light Emitting Diodes

There is a class of conjugated organic compounds and polymers with alternating double (C=C) and single (C–C) bonds which show many of the characteristics of semiconductors. They have energy gaps of about the same magnitude, they can be doped to conduct electrons or holes, and their conductivity is rather low. Valence and conduction bands in inorganic semiconductors are determined by their tetrahedral bonding structures formed by sp^3 hybridization. In organic LEDs the analogue to the valence band is the highest occupied molecular orbital (HOMO). The conduction band corresponds to the lowest unoccupied molecular orbital (LUMO). Whereas in semiconductor LEDs the *p-n* junction is usually formed by *p*- and *n*-type doped regions of the same material; in the organic case the *p* and *n* materials are different. In device operation electrons are injected from the metal cathode and holes from the indium tin oxide (ITO) anode into the electron- (ETL) or hole-transporting (HTL) organic layers, respectively. The carriers move through the organic films by field-assisted tunneling from one molecule to the next (hopping). On their way the carriers "meet" at a single molecule and form an exciton. These excitons recombine across the energy difference between the LUMO and the HOMO. For doping devices the exciton is transferred from the host molecule to a fluorescent guest molecule. Due to quantum-mechanical reasons the electron – hole capture

is expected to produce excitons with spin wavefunctions in the triplet and singlet configurations in the ratio 3:1. Only the singlet state is capable of efficient radiation. The other three long-lived triplet states usually recombine nonradiatively. This limitation and the trapping of light limits the maximum possible external quantum efficiency to 8 % or below unless new mechanisms are found to circumvent these conditions. One way of further increasing the quantum efficiency is the use of a phosphorescent dye, which permits triplets to be used to generate photons. Actual devices already run as high as 6.6 % external quantum efficiency for the red color [28].

Following pioneering work [29], [30], research efforts have been directed at developing efficient organic EL devices based on thin films, driven typically below 10 V. Substantial improvements in efficiency, color, and stability of the devices have been achieved.

Organic EL devices generally are bilayer devices, consisting of a hole-transport layer (HTL) and an electron-transport layer (ETL) sandwiched between current injecting electrodes. Potential barriers at the interface of the two layers localize electrons and holes and thus enhance the probability of their recombination in this area. Also, the channel for radiative recombinations can be further optimized by introducing fluorescent centers near this interface. The two-layer structure is thus extended to include a thin emitting layer (EML) between HTL and ETL. The three-layer structure is particularly useful in tuning the EL colors [31].

The current in the organic layers in the EL device is principally space-charge or injection limited. Space-charge limitation is avoided by using organic films only a few hundred nanometers thick. As ETL organic materials often a complex of 8-hydroxyquinoline with a tris-ligand configuration around the central Al ion (called Alq) is used, while the EML contains a small amount of flourescent molecules, and the HTL is composed of an aromatic amine material. Another successful approach is the use of light-emitting polymer material for the fabrication of flexible full-color displays. Low-barrier contacts are designed by matching the organic layers with electrode materials with appropriate work functions like Mg:Ag or Al:Li as cathode material and ITO for the anode. Figure 15 shows the schematic structures of OLED and PLED devices.

OLEDs and PLEDs are excellent candidates for display application. They have fast response, high brightness, high efficiency, wide viewing angle, and easy gray-scale control. A major problem in manufacturing is the incompatibility of the materials with conventional photolithography for patterning. As a consequence shadow masks are used. The device constituents including the cathodes are very sensitive to moisture and oxygen, so extremely good sealing is required, including the incorporation of some dessicant inside the seal.

4.1.3.3. Electroluminescence in Inorganic Materials

Electroluminescent powder-based devices consist of suitably doped ZnS powder suspended in a transparent dielectric binder and sandwiched between two electrodes, one of which is transparent. Activated by the application of about 150 V a.c., these devices are only employed for low-level flat lighting applications. Their d.c.-driven powder counterparts consist of small grains of doped ZnS with an initial onionskin coating of CuS_2 on each particle, which undergo a forming process after initial activation, which results in a high-field zone in the device where light is generated. Although moderately multiplexible these products have disappeared from the market as information displays.

The only inorganic electroluminescent device on the market is the a.c. thin-film (ACFEL or TFEL) device. It consists of a transparent (glass) substrate with indium tin oxide electrodes, onto which a sandwich of a few hundred nanometers of insulator, 500 nm of phosphor, and again a few hundred nanometers of insulator thin films is deposited. On top of this stack a metallic or transparent electrode is applied.

Conceptually of striking simplicity electroluminescence (EL) in thin films of inorganic semiconductors has nevertheless never gained a significant share of the display market. The main reason is the still poor performance as full-color displays. Although encouraging progress has been made in recent years in improving color phosphor materials with blue and broad-band emissions for ELDs, it is not yet sufficient for a large-scale breakthrough on the market. For

Figure 15. Typical layer structure and materials for A) OLEDs and B) PLEDs

a comprehensive book on inorganic high-field electroluminescent devices, see [32].

The classical EL phosphor is the yellow-emitting ZnS:Mn. This large-band-gap semiconductor is sandwiched between two insulating thin films and operated with a.c. voltage. The power dissipated in generating light is 8 mW/cm^2. Accordingly the power required to generate light from a 10-inch VGA display is just over 1 W, and the luminous efficiency is 6 lm/W.

Two parallel roads have been taken to achieve color EL:

1) The development of an efficient white (broad-band) phosphor that can be filtered to yield red, green, and blue emission (color by white)
2) The development of efficient red, green, and blue primary-color EL phosphors

Efficient red emission (1 lm/W) can be acieved with a combination of the standard yellow ZnS:Mn phosphor and a red filter [33]. The green ZnS:Tb phosphor also has an efficiency near 1 lm/W [34]. In the blue part of the spectrum for some time the efficient SrS:Ce phosphor was available. Actually this phosphor has a blue-green chromaticity and requires filtering to achieve a true blue color. Barrow et al. [35] achieved an important breakthrough by showing that a group of ternary sulfides (thiogallates: MGa_2S_4, M = Ca, Sr, or Ba) activated with Ce are efficient blue-emitting phosphors.

White EL phosphors were first based on the broad emission of the system SrS:Ce,Eu, but the achieved brightness did not satisfy the needs of high-information displays. White emission from stacked layers of ZnS:Mn and SrS:Ce phosphors came close to the luminance level required for filtered-color ELDs [36]. A deep blue emission (and better stability) was claimed for the phosphor SrS:Cu, which in combination with ZnS:Mn emits a true white color [37]. Alternatively to the above thin-film layer structures a structure was proposed with a 30-mm-thick film dielectric layer on a ceramic substrate, which allows higher processing temperatures than glass. On top of this dielectric layer patterned SrS:Ce and (Zn,Mg)S:Mn phosphors are produced, followed by a thin-film dielectric layer, a transparent electrode, and filters which are aligned to the phosphors, thus allowing for better saturation of the blue subpixels [70].

4.2. Light Modulating (Passive) Displays

Passive, nonemissive displays present information by changing the ambient light pattern at the observer. Light radiation can be modulated by changing the amplitude of the electromagnetic wave (absorption), the direction of wave propagation (scattering or refraction), or the polarization of the wave. Detection of polarization changes requires the use of polarizers.

Nonemissive displays are often viewed in reflection. Light is modulated on the way to the reflecting nontransparent mirror and/or on the way back from the mirror to the observer. These reflective passive displays have two distinct features: (1) they require much less power and (2) they do not lose contrast (wash out) in high ambient light. Problems arise, however, if the display is to be read in medium- to low-light conditions and particularly if color is required. Then the displays have to be transmissive, and are supported by a backlight. Thus they gain in visual performance but largely lose the advantage of very low power consumption. To accommodate the different trade-offs transflective passive displays are becoming popular. These displays make use of reflected light under bright ambient conditions and can activate a backlight when the surroundings are not bright enough.

4.2.1. Liquid Crystal Displays

Liquid crystal displays (LCDs) are currently the most important flat panel displays on the market. Liquid crystal displays can be used in a transmissive or a reflective mode, and for some applications in both. The liquid crystal state (mesomorphic state) is an intermediate state between solid and liquid (→ Liquid Crystals). Liquid crystals occur in several mesophases which exist between the isotropic liquid phase and the highly ordered crystalline structure. Technically, the most important mesophases are the nematic (stringlike) and the smectic (soapy) mesophases. Nematic liquid crystal molecules consist of a flexible component such as alkyl groups and a rigid component such as biphenyl group and a cyano group. The cyano group serves to produce positive dielectric anisotropy (the difference between the dielectric constant in the direction of the long axis of the liquid crystal molecule and the dielectric constant perpendicular to the long axis). Molecular design efforts in recent years have involved replacing or modifying the three parts of a liquid crystal to synthesise new liquid crystals. This is illustrated in Figure 16, which shows the main results of chemical modifications on the device performance [38]. Properties that cannot be produced by molecular design are achieved by mixing various liquid-crystal materials, e.g., to increase the practical temperature range.

4.2.1.1. Fundamental Operation

LCDs with the twisted nematic operating mode are one of the earliest technical realizations and still the dominant technology. To build such a device, an orientation layer (polyimide) is applied to the surface of two glasses, equipped with transparent electrodes, and the layer is rubbed. Spacers of about 5 – 8 μm are sprayed onto the surfaces, and a sealing material is applied to the edges of the display The display is assembled by gluing together the two substrates with the rubbing directions orthogonal to each other. When nematic liquid crystals are injected into the gap between the two substrate glasses the director pattern (the unit vector parallel to the average local orientation of the liquid-crystal molecules) changes gradually from the parallel orientation in the immediate vicinity of the top substrate to a 90°-twisted orientation at the bottom substrate. The alignment of the molecules is homogenous with a slight tilt to ensure that all molecules turn in the same direction above threshold. To the outside face of the substrates polarizer films are laminated, so that their polarization axis are either at 90° or parallel to each other.

When light enters the panel it is first linearly polarized and enters the liquid crystal containing gap in a direction parallel to the director of the molecules. The light passing through the first molecular layer rotates along the molecules and enters the second molecular layer with the net effect being that the angle of the linearly polarized light is twisted by an angle equal to that by which the molecular layer is twisted. This occurs repeatedly from layer to layer until at the bottom the linearly polarized light has rotated an amount equal to the twist of the molecules.

Figure 16. Molecular design for liquid-crystal molecules

Having passed the liquid crystal layer the light crosses the second polarizer film, and depending on the arrangement of the film polarization axis it is totally transmitted (normally white mode) or totally absorbed (normally black mode), as is schematically illustrated in Figure 17.

When an electric field is applied to the liquid crystal layer the anisotropy of its dielectric constant causes the long axis of the molecules to turn parallel to the direction of the electric field, and they line up perpendicular to the substrates. If linearly polarized light now enters the liquid-crystal layer it does not undergo any change. Accordingly, the action of an electric field will cause the normally white pixel to turn to dark, since the polarized light is absorbed in the second polarizer film. Vice versa, in the normally dark mode the electric field switches the pixel on.

4.2.1.2. Simple Matrix-Addressed LCDs

The simple *matrix-addressed LCD* consists of two plates of glass with orthogonal rows and columns of electrodes enclosing the liquid crystal material. Scan pulses are applied sequentially to the rows, and data pulses correlated with scan pulses are fed into the columns. A trade-off exists between the number of elements to be multiplexed and both the display contrast and the response rate.

To turn on an LCD picture element, the sum of voltages on the row and column must exceed the turn-on voltage V_t. If the other elements on the same row or column are to remain off, the potential across these elements must stay below V_t. However, liquid crystals are sluggish and exhibit a time-integrated root-mean-square (rms) voltage response rather than an instantaneous response. The Off elements see the integral of all the column potentials, and as the number of rows N increases, they tend to turn on. The permissible root-mean-square On potentials can just barely exceed V_t, while the Off voltages can be only marginally below it [39]. Since the driving potential should be at least 2 – 3 times V_t for good contrast and viewing angle, multiplexing seriously degrades performance. As the electro-optic characteristics are made sharper, a greater number of lines can be addressed.

In LCD matrix displays the driving circuitry sequentially selects the address lines, while the data information is sent simultaneously to all pixels in the selected line. Twisted nematic liquid crystals have relatively slow turn-on times, and they respond to the time average voltage (rms) instead of the instantaneous voltage. A se-

Figure 17. Schematic represemtation of light and dark state in twisted nematic LCDs

lected pixel, which spends most of its time with its driving voltage below threshold voltage, has only a slightly higher rms voltage than an unselected pixel. All contrast must be produced with only this small difference in voltage. This is why a highly nonlinear response is required, as is provided by supertwist (STN) LCDs. Adding some chiral nematic liquid crystals and chiral compounds to nematic liquid crystals causes the nematic liquid crystal to assume a helical structure. A critical factor is the angle by which the helix rotates. The original smooth threshold characteristics can be significantly improved by setting the twist angle to 240 – 270°. This operating mode is referred to as the STN mode.

A drawback of STN is the inherent comparatively long response time (100 – 300 ms) and the chromaticity of the cell. To eliminate the chromaticity double supertwisted nematic cells (D-STN) have been developed. Here a second LC panel containing a helix of the opposite orientation is placed in front of the first device. This technique later gave way to film-compensated STN (F-STN), in which the undesired coloration was compensated for by a phase-difference film.

4.2.1.3. Novel Addressing Schemes for Direct-Addressed STN LCDs

The inherent response time of the display must be many times longer than the refresh time to satisfy the rms response condition. This generally rules out displays with response times short enough to show moving images at video rates. Indeed, if the display uses a slow-responding LC mixture, the difference between Off and On states is never large enough to generate good contrast. If the display uses a fast-responding LC, then the contrast of an individual row begins to fade before the next refresh cycle begins, again deteriorating contrast. This phenomenon is called frame response; instead of responding to the average voltage applied over several frames the LCD reacts to the relatively high voltage row pulse within a frame.

The problem can be avoided by different approaches (Active Addressing [40] and Multiple-Line Selection [41]). Instead of sending the high-voltage pulses sequentially down the rows, a set of predetermined signals is applied to multiple rows simultaneously and a unique calculated analogue voltage is applied to the columns, depending on the state of the pixels in that column. The key is to determine which rows need which signal and to calculate the proper column voltage within the time frame available. An LCD cell is

needed that is capable of switching at video rates (i.e. by decreasing the cell thickness and using fast material).

4.2.2. Reflective LCDs for Low-Power Systems

Reflective color LCD without back light would be the enabling technology for multifunctional portable information terminals with which one could receive and send any information any time at any place. Mechanisms such as phase retardation, rotation of polarization, absorption, light scattering, and Bragg reflection have been used to modulate reflected ambient light. Such displays do not need heavy batteries and represent a promising approach to ″electronic paper″ today. (Further technologies for this application are described in Section 4.2.5).

4.2.2.1. Reflective LCDs with Polarizers

Making use of phase retardation and polarization rotation requires the use of two or at least one polarizer for the LCD. In a simple 90°-twisted nematic cell with two crossed polarizers, the second polarizer is placed between the back substrate and the reflector. It reduces the brightness by about 30 % and causes parallax (double images), limiting the device resolution. If the second polarizer is removed the parallax is eliminated. The light however still has to traverse the polarizer twice, and this limits the throughput to 38 %. A single-polarizer LCD exhibits a better contrast ratio than a nonpolarizer LCD, although its reflectivity is lower. A high contrast ratio is essential for color displays. The single-polarizer LCD offers a compromise between display brightness and contrast ratio, and actually represents the mainstream approach. A comprehensive description of the basic LC modes and design concepts is been given in [42].

4.2.2.2. Polarizer-Free Reflective LCDs

An LCD that does not require a polarizer shows good reflective properties and a wide viewing angle, but the contrast is often limited to values of around 10:1. Three different types of polarizer-free LCDs have been developed: The chiral nematic (or cholesteric) LCD, the polymer-dispersed liquid crystal display (PDLC), and the guest – host (GH) display.

In *cholesteric liquid crystals* the chiral components cause the molecules to spontaneously align on the surface of a helix. These helices are stabilized by the anchoring forces of the orientation layer. If in the voltage-off state the product of the pitch length p of their helical structure and the average refractive index n is equal to the wavelength of the light l (i.e., $\lambda = np$), the Bragg condition of constructive interference is fulfilled, and the material has the property of selectively reflecting light of a specific wavelength. In helical structures the incident white light is decomposed into right and left circularly polarized components, one of which is reflected and the other transmitted. The transmitted light is absorbed by a black layer on the rear inner substrate surface. In the voltage-on state the periodic helical structures are changed to focal-conic and hence the Bragg reflection is interrupted. The incoming light is absorbed by the black layer and the entire pixel appears dark. Cholesteric liquid crystals can form one of three major textures depending on boundary conditions and applied fields [43]: planar, focal-conic, or homeotropic (Fig. 18). With increasing field strength the planar structure first transforms into a focal-conic structure, then into a homeotropic aligned nematic state, which is highly transparent. The planar texture is highly reflective at a preselected wavelength and bandwidth. By introduction of a polymer network or suitable surface treatment of the cell substrates, a domain structure is introduced. This broadens the viewing angle, stabilizes the focal-conic texture to create bistable switching, and introduces a gray-scale regime. The ability of the display to maintain pixels both in the On and Off states once they are written (without refresh) allows for unlimited resolution on a low-cost passive matrix without sacrificing contrast. Full-page-size prototypes [44] have been demonstrated.

In the first engineering samples a total reflection of around 40 % was observed, substantially greater than that of an ordinary reflective twisted nematic LCD. The achievable contrast is determined by the transparency of the focal-conic structure, which can exhibit slight scattering. Different driving schemes are still under

Figure 18. Schematic textures in cholesteric liquid crystal material
a) Light-reflecting planar texture; b) Nearly transparent focal-conic texture; c) Transparent homeotropic texture; d) Transient planar structure

development. Real-time television has already been viewed on a cholesteric display cell at Kent State University [45].

PDLC operation is based on light-scattering induced by the refractive index mismatch between micron-sized liquid crystal droplets and the surrounding polymer matrix [72]. In the normally black mode, the LC droplets scatter light due to index mismatch at zero field and transmit light above a threshold field. (The reverse mode is also possible.) In the transparent mode, due to the application of the electric field, the LC droplets are aligned nearly perpendicular to the substrates, with the refractive index of the extraordinary ray in the liquid crystals matching that of the surrounding polymer matrix. The light passes through the PDLC layer and is reflected from the rear reflector. PDLC devices are much brighter than ordinary reflective twisted nematic cells, but their contrast ratio is lower. A new development is using PDLCs to form switchable reflective holograms. Such gratings are formed by curing a prepolymer in the interference fringes of two coherent counterpropagating laser beams. The periodic variation in intensity results in localized regions of higher and lower polymerization rates. The resulting films have periodic LC domains separated by dense polymer, and consequently a periodic modulation of the refractive index. In the field-off state, diffraction of light due to the presence of the holographic grating is observed. This can be turned on and off by the application of an electric field. Commercial application is however still a few years away [46].

Guest – host displays employ the absorption anisotropy of dichroic dye molecules dissolved in amounts of 1 – 5 % in a liquid-crystal host. The host material is highly transparent for the visible spectrum, whereas the dye dopants absorb one polarization of the incoming light and transmit the other. The use of polarizers has been avoided by, for example, a quarter-wave film behind the rear substrate and the reflector (Cole – Kashnow) or the application of a chiral dopant to form twisted guest – host layers that absorb both polarizations of the incoming light while traversing the doped layer twice (White – Taylor).

4.2.3. Bistable Liquid Crystal Devices

An LCD is called bistable if it assumes two different configurations at zero electric field. Which configuration is displayed depends on the addressing history of the device. The respective two stable states represent minima in the total energy stored. Bistable devices are able to maintain an image memory at zero field, like a printed page of a magazine. Clearly they consume substantially less energy than those in which the

image must be refreshed periodically. The most prominent representative of bistable LCDs is the ferroelectric liquid crystal display.

Optically active (chiral) smectic liquid crystals have a permanent electric dipole moment in the absence of an electric field, and for this reason they are also called ferroelectric liquid crystals (FLCs). The intrinsic polarization of these molecules, which is perpendicular to their long molecular axis (director), has the consequence that when subjected to an external field the molecules respond to the direction as well as the magnitude of the field. The helical structure would average out the direction of the spontaneous dipole, thus suppressing the ferroelectric behavior. Rubbed polymer surface alignment layers, similar to those in supertwist LCDs, remove the helical structure. The spacing between the two glass substrates should be about 2 μm. This spacing is also required for the ferroelectric liquid crystal cell to act as a half-wave plate. The operation of a FLC display depends on the switching of the FLCs dipole, whose orientation depends on the polarity of the addressing pulse.

The FLC molecule cannot simply rotate about its own axis; instead it is constrained to rotate about an imaginary cone (Fig. 19). If the cone half-angle Θ, which is equal to the tilt angle of the molecules in the smectic layer, is approximately equal to 22.5°, then the change in the orientation of the FLC molecules 2Θ is 45°. This is the angular change that produces the optimum values of transmission and contrast ratio [47].

The two main attributes of FLC displays are very fast switching, typically 100 ms per row, and bistability. This property can be made use of to produce a nonvolatile display in which the image is maintained at zero potential. The molecules switch in the plane of the display rather than perpendicular to it (as in supertwist and active matrix LCDs). This leads to a very good viewing angle. The main obstacles in the commercialization of ferroelectric LCDs have been production issues (very small distance between substrate plates), the absence of gray scale, and susceptibility to mechanical shock, although it is said that there are solutions to these problems. In addition to ferroelectric LCDs there are also antiferroelectric LCDs. Yamada et al. [48] have developed a display with gray scale and have demonstrated high-quality video images on a 125×80 mm^2 display.

4.2.4. Active Matrix-Addressed Liquid Crystal Displays (AMLCDs)

4.2.4.1. Fundamental Properties

Active matrix addressing leaves the fundamental twisted nematic operation (Section 4.2.1.1) unchanged and uses pixel-external nonlinear devices to enhance the contrast of large multiplexed displays. The devices do not respond to the rms time-average voltages but rather to the instantaneous peak voltage. Two-terminal (metal – insulator – metal structures) or three-terminal (thin-film transistors) devices act as switches, electrically isolating a pixel until its input voltage exceeds a certain specified threshold. Pixels in active matrix devices are driven at duty cycles close to 100 %. The voltage at the pixel remains practically constant during each frame, as if the pixel were directly driven. The pixel acts as a capacitor, storing the charge and maintaining the voltage during the frame time. Thin-film transistors (TFTs) formed by sophisticated deposition and patterning technologies are now the most frequently used switches in commercially available AMLCDs. A schematic TFT matrix, the equivalent circuitry, the addressing pulse sequence, and the physical layout of an AMLCD pixel is shown in Figure 20 The semiconductor material used for the TFT in most cases is amorphous silicon because it can be fabricated at relatively low temperatures and generates high image quality. The use of poly-silicon material would allow the integration of driver circuits on the same glass plate due to the much higher mobility achievable. The high temperatures necessary to process poly-silicon are not compatible with normal glass substrates. Solid-phase crystallization and excimer laser annealing for large-grain Si crystallisation and special furnace or laser annealing for doping activation are key processes for the advancement of poly-silicon AMLCD technology. For a recent review of the basics of AMLCDs, see [49].

Figure 19. The FLC molecule is constrained to rotate about an imaginary axis

Figure 20. TFT matrix, equivalent circuit, addressing pulses, and physical layout of an AMLCD pixel

4.2.4.2. Manufacturing Issues

AMLCD manufacturers are now working on the fourth generation with significant improvement in substrate size (730×920 mm^2, accomodating, e.g., six 17-inch faceplates). The coming wave of AMLCDs is intended to at least partially replace CRT monitors. This means that competitive size, cost, and performance of the flat displays will be of paramount importance. Manufacturers will ultimately be targeting mother glass sizes of one meter diagonal. They will simplify their TFT processes by lowering the number of photo masks to four and simplify LC-specific fabrication steps such as the preparation of the orientation layer, LC filling methods, and lamination of polarizers and color filters. They will have to develop means to lower the resistance of bus lines. At the same time they are striving to widen the viewing angle and reduce power consumption of the panels. Figure 21 shows a cross section of a presently available color AMLCD module and indicates how the driving circuitry is connected to the glass substrate carrying the TFTs. Mostly anisotropic conducting films are used to connect the ITO pads on the glass to the driver LSIs. A method of growing importance is the use of chip-on-glass architectures.

Many manufacturers are already envisioning the evolution from the near-future implementation of TFT drivers in poly-Si technology to the ultimate system on glass with the signal processing and driving units fabricated all in poly-Si thin-film technology.

4.2.4.3. Viewing Angle Improvements

The viewing angle is a critical problem for large panel liquid crystal displays. Several technologies have been proposed to improve the originally rather narrow and nonuniform viewing characteristic of single-domain twisted nematic, homogenous (LC molecules oriented nearly – depending on pretilt angle – parallel to the substrate), homeotropic (LC molecules oriented perpendicular to the substrate, vertical alignment) cells. Methods of improving the viewing angle can be external, internal, or a combination of both. In external methods the LC cell is provided with a *phase-compensation film* and/or diffusive optics laminated outside the display. In the internal method the LCD structure is modified internally. Whereas external methods are easy to manufacture and accordingly cheap, they do not improve the viewing angle to more than $\pm 60°$. State-of-the-art approaches generally involve both internal modifications and the usage of external compensation films.

One major internal technology is the formation of *multi-domain cells* with reversed LC orientations in each domain. Each pixel is divided, e.g., into four subpixel domains. The generation of these four domains can be done in a variety of ways: reverse rubbing [50], evaporation, photo-alignment [51], or domain control electrodes [52].

A special modification in the case of vertical alignment (VA) cells is the protrusions method. One group has obtained a *multi-domain VA (MVA) cell* by implementing roof-shaped protrusions on both the TFT and color filter substrates. The domains are automatically controlled by the slopes of the protrusions [53].

Another wide-view method is the *axially symmetric-aligned microcell (ASM)*. Here the LC alignment has a spiral distribution and is symmetric with respect to the cell normal. The ASM mode has been applied to a 42-inch plasma-addressed liquid crystal display (see Section 4.2.4.5) [48].

In common twisted nematic cells the applied electric field is in the longitudinal direction, and the tilted molecule directors cause a different phase retardation viewed from either the right or the left direction. This is the origin of the narrow and asymmetric viewing angle. If the electric field is transverse the LC molecule directors are rotated in the plane. This *in-plane switching* was first devised by Kiefer et al. [54] and implemented by Kondo et al. [55].

Standard AMLCDs have five electrodes, three for gate, source and drain of the transistor, one for the pixel electrode, and one common electrode. In most cases the common electrode is formed on the countersubstrate. As shown in Figure 22, in-plane switching uses an interdigital electrode structure. The five electrodes are arranged in two layers on the TFT substrate side. The lower layer carries the gate and common electrodes, the upper one the source and drain electrodes which are co-used as pixel electrodes. This approach avoids the transparent in-

Figure 21. Cross section of a color AMLCD and connection to the addressing circuitry (after [38])

dium tin oxide electrode on the countersubstrate. The electric field is no longer vertically but horizontally oriented, as indicated by the arrows in Figure 22. Under the influence of this field the optical axis of the nematic LC molecules deviates from the polarization axis and the transmittance of incident light through crossed polarizers is gradually increased. Horizontal and vertical viewing angles of 70° have been achieved at a contrast ratio of 10.

Another implementation of a wide viewing angle cell is the *film-compensated p-cell*. Basically p-cells resemble homogenous cells. The difference is that in homogenous cells the directions of the pretilt angle at the upper and lower substrate are parallel, whereas in p-cells the directions of the pretilt angles of the upper and lower substrate are antiparallel. These opposite pretilt angles result in a rather wide and symmetric viewing angle. As the applied voltage increases the LC directors go through splay and then bend formation. With proper phase compensation (e.g., biaxial retardation film) the *optically compensated bend (OCB) cell* exhibits a wide and nearly symmetric viewing angle with fast response times [56].

4.2.4.4. System Performance

The overall transmissivity of AMLCDs is determined by the transmissivities of the glass (95 %), the polarizers (35 %), the color filters, (25 %), and the cell aperture (that portion of the cell which is transparent to light), which depending on design can vary between 40 and 65 %. As a result the overall transmissivity of the cell is not more than 3.3 – 5.0 %. A major research goal for AMLCDs is to improve transmissivity to reduce power consumption. Two other targets for further power reduction are improvement of the efficiency of backlights and reduction of the power consumption of the drive circuit unit. Backlights consume about 70 % of the total power necessary to operate a transmissive AMLCD module. Therefore, for portable applications much research effort still goes into the improvement of reflective color AMLCDs. Up to now the reflectance of such devices reaches only about 40 % as compared to newspapers or magazines, which achieve 60 % and more [71].

Improving legibility, particularly under conditions of low ambient light, requires some form of either front- or backlight illumination. Transflective AMLCDs are characterized by a reflective layer behind the LC layer (as seen from the viewer) that is structured to allow the additional backlight illumination pass through the reflective layer, e.g., via holes. They retain good picture quality under all ambient-light conditions at reasonable energy consumption.

Figure 22. Cross section of a conventional AMLCD (a) and of an in-plane switching AMLCD (IPS TFT) (b). In the IPS version (c) the common electrode is located in the gate electrode layer. d) Planar arrangement of c) (after [55])

4.2.4.5. Plasma-Addressed Liquid Crystal Displays

Despite their immense success in the portable display area and the anticipated large market share they will conquer in the monitor market in the near future it is not predicted that AMLCDs will be available as meter-sized panels for consumer HDTV in the next few years. The scaling difficulties of photolithography and metallization to sizes larger than 40 inches can elegantly be bypassed by a new approach called plasma addressed liquid crystal (PALC) [57], [58]. PALC uses the electrical switching properties of an ionized gas to actively address the liquid crystal pixels. In the integrated LCD/plasma structure of the PALC, each scan line is defined by a plasma channel. The cathodes in the channels are sequentially scanned by applying a plasma discharge voltage that produces a full plasma within several microseconds. The analogue video signals are fed to each column electrode. Except for the one row in which the gas is ionized, the analogue voltage has no effect on the light transmissivity of the liquid crystal since there is no electrical connection or conductor on the bottom side of the liquid crystal. Along the line above the ionized channel, however, the pixel capacitance can charge to the value determined by the data voltage. In effect, the plasma completes the electrical circuit between the data electrodes and the grounded channel electrode. Kakizaki et al. [59] have presented a 25-inch PALC display for wall-hanging TV with 1.8 lm/W light efficiency, 250 cd/m^2, and high contrast, even in bright ambient light.

4.2.5. Microparticle-Based Displays

The common basis of all microparticle-based display techniques discussed here is the manipulation of small objects such as pigments or rotating microscopic balls by means of electrical forces. The mechanical manipulation of these objects allows for a spatial modulation of the optical properties of display cells, such as their reflectance or transmission behavior for light. In the following, the most promising emerging techniques in this field are reviewed and several alternative approaches are discussed briefly.

4.2.5.1. Electrophoretic Displays

The electro-optical effect used in these types of display cells results from the movement of charged microparticles in a colloidal suspension.

The migration of small charged particles through a liquid induced by an electrical field is known as electrophoresis. Since the pigments are chosen to have reflectance properties different from those of the liquid, the overall optical appearance varies depending on the distribution of the pigment particles in the volume of the display cell. Research activities on these electrophoretic displays (EPDs) were already reported in the early 1970s [60]. This nonemissive display technology offers a very wide angular viewing range and high contrast ratio over a wide range of illumination. After a slowdown in the 1980s recently considerable effort has been spent on the development of prototypes with properties comparable to printed paper. Hence the popular terms "electronic ink" or "electronic paper".

As shown in Figure 23, the EPD suspension is commonly composed of a darkly dyed liquid with low reflectivity, whereas the microparticles are of a light color. For the microparticles, titanium dioxide particles with sizes ranging from the submicrometer regime to several micrometers are used. When a thin layer of this suspension is sandwiched between two parallel electrodes, of which at least that directed towards the observer is transparent, the particles either move to the top or to the bottom electrode, depending on the polarity of the applied field. The observer either sees the opaque dark dye (off state) or the reflective white particles (on state). Since this effect is only controlled by an electric field perpendicular to the electrodes, the addressing of many pixel elements can be realized in parallel by means of appropriate electrode structure. One of the most important advantages of EPDs with respect to energy efficiency is the bistability of the display cells, i.e., the cell remains in its actual state (on or off) after the electric field has been removed. This is achieved by matching the densities of the suspension and the microparticles and thus establishing gravitational stability. Mechanical shocks or thermal influences will disturb this stability. In general, the resulting image contrast is determined by the dye concentration in the suspension, by the thickness of the layer, and by the effective electrical field which is applied to the electrophoretic layer.

When the particles are bunched together or even compressed, the danger of agglomeration and clustering occurs at high electric fields. This has a negative effect on lifetime and quality of the display cell. Therefore, the additional introduction of repulsive forces is necessary to prevent the individual microparticles from sticking together. Colloidal suspensions inherently tend to be unstable. The large surface free energy is reduced as soon as the particles bunch together, which in turn enlarges the attractive forces. Establishing a colloidal stability of the suspension is the most crucial aspect in EPDs and can be achieved by electrostatic or by steric repulsion. While electrostatic repulsion is based on a precise charging of the pigments, steric repulsion is accomplished by covering their surfaces with special polymer molecules. Finally, dye, solvent, and the microparticles must be prevented from interacting chemically.

Several proposals for modifications of cell design and electrode arrangements have been made, such as etched cavities and walls for each display cell for a compartmentation of the particles. In addition to these architecture-related approaches, a materials-related approach in which the electrophoretic suspension is confined in microcapsules (microencapsulation) has been very successful [61]. The microcapsules, with typical diameters between 30 and 300 μm, result from in situ polycondensation of urea and formaldehyde. The capsules have mechanically strong, optically transparent walls with a relatively high dielectric constant. This technology is compatible with conventional techniques like screen and ink-jet printing. The schematic structure of the microencapsulated EPD is shown in Figure 24

4.2.5.2. Rotating Ball Displays (Gyricon)

The basic operating principle of a Gyricon display is depicted in Figure 25. A clear and transparent elastomer sheet is sandwiched between two opposite electrodes. Small balls or beads are randomly dispersed in this substrate sheet, each embedded into a liquid-filled cavity. The balls are composed of two different materials resulting in a structure of two hemispheres with contrasting color and opposite electrical charge. Thus, each ball has a macroscopic electrical dipole character and is free to rotate within its cavity when an electrical field is applied. The observer thus sees either the dark or the light side of the balls, which finally produces an image. For ball sizes of 10 μm and a thickness of the sub-

Figure 23. Schematic structure of an electrophoretic display. The white, negatively charged microparticles are suspended in liquid dyed dark blue and can modulate the reflectivity of the display surface under the action of an electric field.

Figure 24. The microencapsulation of particles in the electrophoretic cell successfully solved the degradation problem due to particle agglomeration

strate sheet of 60 µm, minimum programming voltages of between 50 and 150 V have been reported [62].

5. Projection Displays

In a projection display the image is not viewed directly but enlarged through an optical system and projected on a screen. The two major configurations of projection displays are *front projection* (viewer and projector on the same side of the reflective screen) and *rear projection* (viewer and projector on opposite sides of the transmissive screen). According to the mechanism used to generate the image three categories are distinguished: 1) CRT projection (image formed on the CRT face-plate), 2) light valve projection (light valve on which the image is produced modulates the light of a light source), 3) laser projection (image generated on screen by laser beam deflection).

Figure 25. Principle of a Gyricon rotating ball display. Small hemispheric bichromal balls are dispersed in a thin elastomer sheet. Each ball is placed in an oil filled cavity and freely rotates to adjust its polarity to an applied field.

5.1. Projection CRT

In the standard configuration still widely used today the output of three CRTs with red, green, and blue phosphors are collected by three optical lenses and focused onto a screen. The lenses are often coupled to the CRT faceplates by index-matched fluids to enhance throughput and to provide cooling for the monochrome, shadow-maskless CRTs, which are driven at high current. Lenses are often lenticular projection lenses with contrast-enhancing black stripes. The optics of the lenses and the screen are designed to converge the three color images and direct the image to the viewer in spite of the off axis projection. Limiting factors of this mature technology include the resolution/brightness trade-off inherent in CRT technology. As the electron beam current is increased space charge repulsion within the beam causes beam "blooming", and light scattering in the CRT phosphor itself further lowers the spatial resolution.

Taking the minimum electron beam spot size to be 0.23 mm, a typical 7-inch CRT (with 130 to 140 mm usable diagonal) is capable of only 450 – 490 distinct spots in a horizontal scan line.

The flexibility provided by the multisync raster scan of a CRT display is a significant advantage when displaying signals with different formats and resolutions. Matrix displays have fixed format and resolution and consequently must incorporate image scaling and format conversions.

5.2. Liquid Crystal Projection

The development of small, high-resolution liquid crystal light valves has led to the successful introduction of LC projection displays for use in conference rooms and portable applications. Amorphous, polycrystalline, and single-crystal silicon active matrix arrays have been used to control the LC layer. As higher resolutions are demanded the trend is to polycrystalline single-crystal silicon address circuitry. The general idea of these projectors is to illuminate the light valve by an intense arc lamp and to magnify and project the transmitted or reflected image onto a viewing screen. Since single-crystal silicon is opaque at visible wavelengths, liquid crystal on silicon (LCOS) devices can only operate in reflection. (An exception to this is the silicon on insulator transfer technology for microdisplays [63]).

5.2.1. Transmissive Projection LCDs

The current market for front projection displays for business applications is dominated by polysilicon light valve technology. This technology

is similar to that described in Section 4.2.4. The ability to integrate driver circuits in the poly silicon material has been important in enabling the technology to reach rather high resolution in an economical package. The AMLCD light valves are typically one inch in size and have pixel sizes ranging from 20 to 40 µm. Considerable effort has been spent on improving the optical throughput (aperture and microlens arrays) and the optical shielding of the active circuits (elimination of photo-excitation) in the device.

The common optical layout for AMLCD projectors provides for the collection of light from a small arc lamp and its division into RGB components. Each color is then separately modulated in transmission by an AMLCD light valve. The resulting three images are recombined into a full color image by a dichroic color-combining x-cube. Finally the image is magnified and projected to the screen. Alternatively, tilted dichroic mirrors can be used to direct the three color components of an illumination system to a single AMLCD light valve containing RGB subpixels.

In addition to the optical components like dichroic mirrors and x-cubes, recently very significant improvements have been achieved in the arc lamp and illumination optics. Small arcs for the efficient collection and focusing ofthe light on the small light valve and long lamp life were the main development goals. Since AMLCDs use polarized light, 50 % is immediately lost from the unpolarized lamp light. In principal this "wrong"-polarization component can be recovered by smart polarization conversion systems, which can improve the system throughput by as much as 80 % [64].

5.2.2. Reflective Projection LCDs

Liquid crystal on silicon (LCOS) light valves have been developed for applications ranging from highly mobile microdisplays to high-brightness, high-resolution projection displays. These devices employ an active matrix array manufactured with standard CMOS processing on single-crystal silicon. The array transistors supply the desired voltage to reflective aluminum mirrors rather than to the ITO transmissive electrodes as in poly-Si AMLCDs. Since the layout of the reflective mirror is made to cover row and column lines and the circuit itself it is evident that this design has an aperture ratio advantage over transmissive designs. In fact aperture ratios of about 90 % are routinely achieved. The CMOS transistor array fabrication is followed by a few levels of additional processing which provide the light-blocking layer, the reflective mirrors, and their contacts to the transistor array. The use of chemical mechanical polishing, a technique developed for multilevel wiring on VLSI circuit chips, provided a major advance in the performance of LCOS devices because of the requirement that the mirrors be highly specularly reflecting. One great advantage of LCOS is its scalability to small pixels and hence to small and inexpensive devices. Further advantages of the technology are the good thermal conductivity of silicon, which helps to avoid problems associated with heating, and the ability to inegrate function by using high-quality CMOS circuitry on the array chip.

A variety of LC modes, including twisted nematic, vertically aligned homeotropic, polymer-dispersed liquid crystal, and ferroelectric, have been successfully implemented. The optical architecture must effectively separate the incident illumination from the reflected image. This is usually done by three polarizing beam splitters in the RGB channels, which polarize and analyze the light and separate the incident light from the reflected image.

5.3. Micromechanical Light Valve Projection

Three separate light valve technologies based on arrays of moving micromechanical devices, which either reflect or diffract light, have been developed. Switching is fast enough in each of these technologies to allow for color sequential operation. The optical throughput is larger than in polarization-sensitive LCD devices, since these devices do not require polarized light.

The activated mirror array consists of an array of piezoelectrically activated thin-film micromirrors [65]. These mirrors are driven by an active matrix array fabricated under the mirrors by CMOS technology. The angular deflection of the mirrors is a function of the supplied voltage, giving an analog light intensity versus voltage response behaviour.

The grating light valve consists of a large number of individually addressed small diffraction gratings [66]. Depending on the voltage applied the grating acts on the illuminating light either as a reflecting mirror or as a diffracting element with an analog diffraction response behavior. A Schlieren optical system allows the first-order diffracted light to enter the projection lens while rejecting the reflected light. The linear array of diffraction gratings is illuminated by a laser source.

Whereas the above-mentioned two technologies have not yet entered the market, digital micromirror devices (DMD) and the digital light processing (DLP) [67], [68] have had significant commercial impact. The DMD consists of an array of many individual reflecting $17 \times 17\,\mu m^2$ micromirrors, each which can be electrostatically deflected by address voltages. The mirrors are binary. In one state they reflect incident light into the projection lens, and in the other do not. During operation light from an arc lamp is chopped by a color wheel into its RGB components which sequentially illuminate the single DMD device. The device is driven rapidly with the appropriate RGB image data. The three monochrome images are reflected into the lens and temporally averaged by the human visual system to form a full color image. Gray scale is achieved by binary pulse width modulation.

1. Introduction

Dithiocarbamic acids are monoamides of dithiocarbonic acid. As a rule, one or both of the hydrogen atoms on the nitrogen atom are replaced by alkyl, aralkyl, cycloalkyl, or aryl radicals; the amide nitrogen atom may also belong to a ring:

Acyl- and thioacyldithiocarbamic acids have also been described:

Industrially important derivatives of dithiocarbamic acids are ammonium and metal salts, esters, thiuram sulfides, thiocarbamoylsulfenamides, and a number of other products. They are used mainly as vulcanization accelerators in the rubber industry and as fungicides in agriculture.

2. Physical and Chemical Properties

Free dithiocarbamic acid is unstable in the solid state (*mp* 35.7 °C) and in solution. Thermal decomposition results in carbon disulfide, hydrogen sulfide, and ammonium thiocyanate [11].

Free *N*-substituted dithiocarbamic acids are also unstable. However, diphenyldithiocarbamic acid [12] is stable, as are several acyldithiocarbamic acids, such as formyl- [13], 2-ethoxybenzoyl- [14], and furoyldithiocarbamic acid [14], as well as 2-pyrrolidone-1-dithiocarbamic acid [15] (Table 1); these acids can be produced from the alkali salts by acidification with HCl gas in solvents such as ether. *N*-Thiobenzoyldithiocarbamic acid cannot be obtained by this method [16].

Salts of dithiocarbamic acids are more stable than the free acids [17]. The physical properties of some alkali-metal, heavy-metal, and ammonium dithiocarbamates are listed in Tables 2, 3, 4. Salts of unsubstituted and *N*-monosubstituted

dithiocarbamic acids decompose on heating and are sensitive to oxidation (see Section 4.6.3). Derivatives of the tautomeric imide form of N-monosubstituted dithiocarbamic acids are also known [14].

[18] , [19], [20], [21], [22]

Salts and derivatives of *N,N*-disubstituted dithiocarbamic acids are very stable. These salts (especially the heavy-metal salts) are strongly colored; they are often volatile and soluble in organic solvents. For example, the copper, nickel, and cobalt salts of *N,N*-diisobutyldithiocarbamic acid can be distilled at low pressure. These compounds are apparently internal complexes.

Reactions of dithiocarbamate salts to form esters, thiuram sulfides, and other derivatives are discussed in detail in Chapter 4. All dithiocarbamic acids and their derivatives are cleaved by mineral acids to carbon disulfide and ammonium salts of the mineral acid. This reaction can be used to determine the structure of unknown derivatives [23].

3. Manufacture of Dithiocarbamate Salts

The parent compound in this series, ammonium dithiocarbamate [*513-74-6*], is prepared most easily from ammonia and carbon disulfide in alcohol or an ester solvent [24]. *N*-Alkyldithiocarbamic acids can be obtained as ammonium salts from two moles of a primary amine and one mole of carbon disulfide:

If the reaction is carried out in the presence of an alkali or alkaline-earth hydroxide, the corresponding metal salts are formed. To prepare *N*-aryldithiocarbamates a strong base is required; otherwise *N,N*-diarylthioureas are formed. Heavy-metal dithiocarbamates are obtained from ammonium or alkali dithiocarbamates and the corresponding heavy-metal salts in aqueous solution, or directly by reaction of an aromatic amine and carbon disulfide in the presence of finely divided metal oxide [25]. The deeply colored salts of formyldithiocarbamic

acid are produced from potassium formyldithiocarbamate [18].

Amine and ammonium salts of *N,N*-disubstituted dithiocarbamic acids are produced from carbon disulfide by reaction with two equivalents of amine or one each of amine and ammonia. An example is the piperidinium salt of pentamethylenedithiocarbamic acid, which is used as a vulcanization accelerator.

Guanidine and arylguanidine react analogously [26]; hydroxylamine derivatives have also been described [27].

Alkali and heavy-metal salts of *N,N*-disubstituted dithiocarbamic acids are produced like the monosubstituted salts [28], [29].

Diamines react with two moles of carbon disulfide to yield bis(dithiocarbamates). Zinc, iron, and copper ethylenebis(dithiocarbamates) are used as fungicides and nematocides [30]. With one mole of carbon disulfide, diamines form inner salts or mixtures of inner salts and amine salts of bis(dithiocarbamic acids). Such mixtures are produced by piperazines [31].

Hydrazine reacts with one mole of carbon disulfide in the presence of alkali hydroxide to form alkali salts of aminodithiocarbamic acid (dithiocarbazic acid) [32]:

With two moles of carbon disulfide, salts derived from the tautomeric imide form are obtained [33]:

Metal salts, particularly zinc dithiocarbamates, are used as vulcanization accelerators, oil additives, bactericides, and fungicides.

4. Transformation Products

4.1. Thiuram Sulfides

4.1.1. Thiuram Disulfides

The oxidation of salts of dithiocarbamic acids usually gives thiuram disulfides (bis(aminothiocarbonyl)disulfanes) [34–36]. Table 5 lists physical properties of some thiuram sulfides. Only the tetraalkyl derivatives are stable. Oxidizing agents include iodine, bromine, hydrogen peroxide, and potassium peroxodisulfate [37]; ammonium peroxodisulfate [38]; sodium tetrathionate [39]; and chlorine or bromine in the presence of buffers [40]. The colorless compound tetramethylthiuram disulfide, for example, is obtained from sodium dimethylthiocarbamate and hydrogen peroxide [41]:

Other methods use hypochlorites [42], sodium nitrite [43], oxygen in the presence of catalysts such as copper or manganese salts [44] (see also Section 4.6.3), or electrolytic oxidation [45]. Tetraalkylthiuram disulfides are powerful vulcanization accelerators [46].

N-Acyl derivatives are also known. For example, oxidation of *N*-methyl-*N*-formyldithiocarbamate with iodine in ether yields the corresponding thiuram [47]:

N-Methyl-*N*-thioformyldithiocarbamate gives a cyclic, pale yellow thiuram (*mp* 108.5 °C) [48]:

N-Thioformyldithiocarbamate, however, yields 1,2,4-dithiazole-3-thione (*mp* 73–75 °C) [47]:

Oxidation of *N*-(2-ethoxybenzoyl)dithiocarbamate gives the corresponding disulfide (*mp* 138 °C) which, when heated in the presence of pyridine, yields 2-ethoxybenzoyl disulfide (*mp* 137–139 °C) [14].

4.1.2. Thiuram Monosulfides

Thiuram disulfides may lose one sulfur atom to form thiuram monosulfides (bis(aminothiocarbonyl)sulfanes), which are also used as vulcanization accelerators [46].

Tetramethylthiuram disulfide gives the yellow monosulfide on heating with triphenylphosphine [49] or potassium cyanide [50] (Fig. 1, Reaction 1). The monosulfide can also be obtained directly from sodium dimethyldithiocarbamate by reaction with phosgene [51], [52] or cyanogen chloride [51], [53] (Reaction 2). Another method uses the ammonium dithiocarbamate and thiocarbamoyl chloride [54] (Reaction 3).

4.1.3. Thiuram Trisulfides and Tetrasulfides

Sulfur dichloride reacts with alkali dithiocarbamates to form thiuram trisulfides (bis(aminothiocarbonyl)trisulfanes). Disulfur dichloride gives the corresponding tetrasulfides, e.g., the tetrasulfide of pentamethylenedithiocarbamic acid, an important vulcanization accelerator [55]:

4.2. Thiocarbamoylsulfenamides

Thiocarbamoylsulfenamides are obtained from *N,N*-disubstituted dithiocarbamates by mild oxidation with iodine in the presence of primary or secondary amines [56] or by electrolytic oxidation [57]:

These compounds are used as vulcanization accelerators, fungicides [58], and bactericides [59]. Thermolysis removes one atom of sulfur to give thioureas. The morpholine derivative is manufactured by oxidation with sodium hypochlorite [60–69].

Substituted thiocarbamoylsulfenamides are obtained by reaction with isocyanates [70]:

Polymeric thiocarbamoylsulfenamides have also been reported [71].

4.3. Thiocarbamoyl Chlorides

Thiuram disulfides react with chlorine in organic solvents to give disubstituted thiocarbamoyl chlorides, which are useful intermediates [72], [73].

The methyl groups can be replaced by ethyl, propyl, butyl, or phenyl groups; the nitrogen can also be part of a piperidine ring [74]. Alternatively, thiocarbamoyl chlorides can be obtained from amines and thiophosgene [75] or by chlorination of thioformamides [76]. Further chlorination leads to iminium salts [77]:

Figure 1. Syntheses of tetramethylthiuram monosulfide

4.4. Dithiocarbamic Acid Esters

Dithiocarbamic acid esters (dithiourethanes) are used in agriculture as nematocides, fungicides, and herbicides. Physical properties of some dithiocarbamates are given in Table 6. The most important methods of preparation are (1) alkylation of alkali dithiocarbamates with halogen compounds or other alkylating agents and (2) insertion reactions of carbon disulfide with tertiary amines.

Suitable halogen compounds include alkyl chlorides, benzyl chloride [78], phenacyl chloride [79], acyloxymethyl chloride [80], and allyl chlorides [81]. For example, the reaction of sodium *N*,*N*-dimethyldithiocarbamate with 1,3-dichloro-2-butene gives dimethyldithiocarbamic acid 3-chloro-2-butenyl ester, which is used as a herbicide:

Other alkylating agents are (1) halogenated aldehydes, ketones, and chlorohydrin [78]; (2) dihalogen compounds such as benzal chloride [82] and 1,3-dichloropropane [83]; (3) trihalogen compounds such as cyanuric chloride [84] and chloroform [85]; and (4) polychlorinated compounds [86]. The reaction of an alkali dithiocarbamate with chloroform, for example, yields an amino diester and carbon disulfide:

High yields are also obtained from alkali acyldithiocarbamates and alkyl halides [48], [87], [88]:

Arylation is possible with strongly activated halobenzenes such as 2,4-dinitrochlorobenzene [82] or with diazonium salts [89]. Phenyl esters are also produced by reaction of phenyldithioformic acid chloride with amines [90]. *o*-Phenylene diesters are obtained from *o*-nitrophenyl monoesters by substitution of the nitro group [91].

Sulfenyl halides [92] and thiosulfates [93] react similarly with alkali dithiocarbamates to form thiocarbamoylalkyldisulfanes:

Dithiocarbamic acid esters are also obtained by reaction of thiocarbamoyl chlorides with thiophosphates [94] or by addition of thiols to isothiocyanates [95], [96].

Table 6. Physical properties of dithiocarbamic acid esters

* Boiling point at 0.01 mm Hg (1.3 Pa).

Vinyl esters can be prepared from phenolates [97]:

Alkylation of ammonium dithiocarbamates with epoxides is also possible [98]:

Styrene oxide and sodium diethyldithiocarbamate react similarly [99]. At low temperature, epichlorohydrin reacts like an epoxide to form the dithiocarbamic acid ester; when heated in the presence of a tertiary amine, this ester rearranges to the thiocarbamate [100]:

Whereas primary or secondary amines react with carbon disulfide to form mono- or disubstituted salts of dithiocarbamic acids (see Chap. 3), some tertiary amines such as aziridines form cyclic esters. For example, *N*-phenylthiazolidine-2-thione is obtained from *N*-phenylaziridine [101]:

β-Amino ketones [102] and benzylamines [103] also react with insertion of carbon disulfide; for example, 2,6-di-*tert*-butyl-4-dialkylaminomethylphenols form esters that are used as stabilizers and intermediates [104]:

Silylamines also give insertion products, but no insertion is observed with silylaminophosphine [105]:

Methylenediamines, such as bis(piperidino)-methane, and carbon disulfide form aminomethyl dithiocarbamates [106]:

Piperidinomethyl carbamates can also be produced from methylolpiperidine and salts of dithiocarbamic acids [107]. Methylene bis(dithiocarbamates) are obtained from formaldehyde and dithiocarbamic acids in acidic solution [108]:

Bis(dithiocarbamates) are also formed by cleavage of ethylene trithiocarbonate with amines [4], [109]. Benzothiazolyl dithiocarbamates, which are used as accelerators for rubber, can be obtained in high yield from benzothiazole disulfide and thiuram disulfide in the presence of sodium cyanide [110]:

Dithiocarbamates are also prepared by addition of dithiocarbamic acids to unsaturated compounds such as vinylsulfonates [111], vinyl ether [112], acrylonitrile [113], vinylpyridine [114], mesityl oxide [115], acetylenedicarboxylate [116], acetylene ketones [117], and even acetylene [118]:

Unsaturated dithiocarbamates have been used in the stereoselective synthesis of polyenes [119]. The chlorination of monosubstituted dithiocarbamates leads to isocyanide dichlorides and removal of the sulfur [120], [121]:

4.5. Heterocyclic Compounds

Five-membered Heterocycles. Dithiocarbamic acid and its salts react with

monochloroacetic acid to yield first the dithiocarbamic acid ester and then rhodanine [122], [123]:

Rhodanine reacts with aldehydes [122], [124]; the products are stimulants [125]. Thiorhodanine (thiazolidinedithione) [126], *N*-aminorhodanine [127], and other substituted rhodanines [128], [129] have also been prepared. Certain rhodanines act as cross-linking agents [130].

Ammonium dithiocarbamate and α-halogenated ketones or aldehydes give 2-mercaptothiazoles; *N*-alkyldithiocarbamates form *N*-alkylthiazoline-2-thiones [129], [131]:

The reaction of dithiocarbamic acid methyl ester and chloroacetaldehyde leads to 2-methylthiothiazole, which is easily converted to thiazole with lithium in liquid ammonia [132]. Further thiazoline-2-thione syntheses have been described [133], [134].

Thiazolidine-2-thione is prepared by treating methyl thioxanthate with bromoethylamine [135]; substituted thiazolidine-2-thiones are obtained by heating aminoethanols with carbon disulfide [136]:

N-Methylthiazolidine-2-thione [137] is a good accelerator for polychloroprene.

Bis(carboxyaminoethyl)disulfane and carbon disulfide yield carboxythiazolidine-2-thione [138]:

The reaction between acylaminodithiocarboxylic acid esters and aziridine leads to 2-acyliminothiazolidines [139]:

Thiazolotriazinium salts are prepared from dithiocarbazic acid methyl ester [140]. Aroylcarbimidodithioates easily cyclize with hydrazine to triazoles [14]:

The cyclization of *N*-methylquinoxalinium iodide with dithiocarbamates gives tetrahydrothiazoloquinoxalines [141]:

Six-membered Heterocycles. The reaction of *N*-methyldithiocarbamic acid with propiolic acid after several steps leads to 3-methyl-3,4-dihydro-4-oxo-2-thioxo-2*H*-1,3-thiazine [142]:

Heating this compound with primary amines gives 2-thiouracyls. 3*H*-1,3-Thiazine-2,6-

dithiones have also been reported [143]. Saturated six-membered rings are synthesized by reaction of dithiocarbamic acids with acrylonitrile [144] or propiolactone [145]. Acrylamides and carbon disulfide give 2-thioxoperhydro-1,3-thiazin-4-ones [146] and other derivatives [147]:

Oxidation removes the thione sulfur [148]:

3-Amino-2-thioxotetrahydro-1,3-thiazin-4-ones are obtained from hydrazine or its derivatives [149]:

1,3-Thiazines can also be prepared from thioureas [150]:

Reactions at the nitrogen atom of unsubstituted 1,3-thiazine-2-thione have been reported [151]. Mercaptothiazines are produced from ammonium dithiocarbamate and α,β-unsaturated ketones; the reaction of mesityl oxide with dithiocarbamic acid gives 2-mercapto-4,4,6-trimethyl-4*H*-1,3-thiazine [152]:

Thiadiazinethiones are produced in high yield by condensation of *N*-monosubstituted ammonium dithiocarbamates with aldehydes. For example, the reaction of methylammonium *N*-methyldithiocarbamate with formaldehyde in water gives 3,5-dimethyltetrahydro-2*H*-1,3,5-thiadiazine-2-thione, an accelerator for polychloroprene [176], in 90 % yield [153]:

The corresponding *N*-benzyl derivative, known as sulbentine, is an antimycotic agent [154]. The reaction of methylamine and aminoacetic acid with carbon disulfide and formaldehyde yields 3-methyl-5-carboxymethyltetrahydro-2*H*-1,3,5-thiadiazine-2-thione, a nematocide [155].

4.6. Other Derivatives

4.6.1. Dithiolanylium Salts

2-Dialkylamino-1,3-dithiolanylium salts are prepared by reacting sodium *N*,*N*-dimethyldithiocarbamate with 1,2-dichloroethane in tetrahydrofuran in the presence of sodium perchlorate [156]:

These compounds react with many nucleophiles [156], [157] (see Fig. 2). Unsaturated dithiolium salts can be used to prepare tetrathiafulvenes [158] and 1,2-dimercaptoalkenes [159].

4.6.2. Alkylthioformimidic Chlorides

Alkylthioformimidic chlorides are obtained from *N*,*N*-dialkyldithiocarbamic acid esters and phosgene [160]:

Figure 2. Reactions of 2-dialkylamino-1,3-dithiolanylium salts with nucleophiles

These salts are very reactive; for example, methylthioformimidic chloride and pyrrole give a 2-pyrrolyl derivative of methylthiocarboximidic chloride [161].

4.6.3. Isothiocyanates, Isocyanates, and Thioureas

Isothiocyanates (mustard oils) can be produced from monosubstituted salts or esters of dithiocarbamic acids by oxidation or heat (see also Section 4.1.1 and → Thiocyanates and Isothiocyanates, Organic) [162], [163]:

N-Acyl and *N*-thioacyl derivatives react differently (see Section 4.1.1).

Isocyanates are produced from monosubstituted dithiocarbamates by reaction with phosgene or chloroformates (→ Isocyanates, Organic) [164]:

Thioureas can be obtained from isothiocyanates and primary or secondary amines, by pyrolysis of thiuram disulfides [165], [166], or from dithiocarbamate salts [167] (→ Thiourea):

The synthesis of ethylenethiourea, an accelerator for polychloroprene, also proceeds via a dithiocarbamate salt:

N-Substituted ethylenethiourea derivatives have also been described [168].

4.7. Photolysis of Dithiocarbamates

Irradiation of acyl dithiocarbamates gives acyl and dithiocarbamic acid radicals [169]:

These radicals can initiate polymerizations of olefins. The living radical photopolymerization of styrene with the aid of benzyl *N*,*N*-dialkyldithiocarbamates has also been described [170]:

Other dithiocarbamates have been proposed as photoinitiators for methyl acrylate [171].

5. Uses

5.1. Vulcanization Accelerators

Thiuram sulfides and salts, especially zinc salts, of *N,N*-dialkyldithiocarbamic acids are vulcanization accelerators for natural and synthetic rubber [46], [172], [173]; some examples of commercial products are given in Tables 7 and 8. Water-soluble derivatives are used in low-temperature processing of latex. Thiuram disulfides and polysulfides give heat-resistant rubber products. Sodium and potassium dimethyldithiocarbamates are modifiers in emulsion polymerization [174]. 4-[(Morpholinothiocarbonyl)thio]morpholine is a vulcanization accelerator which gives good resistance to reversion and low compression set [175]. Thiadiazines are also utilized as accelerators [176].

Dithiocarbamic acids are intermediates in the production of thioureas, particularly ethylene-, *N,N′*-diphenyl-, and tetramethylthiourea, which are used as accelerators for polychloroprene. Dust production has been reduced by formulation as polymeric granules. Under certain circumstances, thioureas can be injurious to health (see Chap. 6) [177]; 3-methylthiazolidine-2-thione is a polychloroprene accelerator that does not have this disadvantage [137]. Other nonhazardous vulcanization accelerators have been studied [178].

5.2. Pesticides

Salts and derivatives of various dithiocarbamic acids are used as fungicides, nematocides, or bactericides (Table 9). These compounds liberate mustard oils or dialkyldithiocarbamic acids [179], [180]. Dithiocarbamate pesticides have been the subject of intensive metabolic [181], [182] and environmental [183–186] investigations. Analytical questions are discussed in [187].

5.3. Medical Applications

Tetraethylthiuram disulfide, known as disulfiram, is a withdrawal agent used in the treatment of alcoholism (Table 10). Nontoxic penicillins containing a dithiocarbamic acid structure are effective against penicillin-resistant organisms [188]. Dithiocarbamic acid derivatives are also used as antimycotics [154], [189] and nickel-poisoning antidotes [190] (see Table 10).

A broad spectrum of activity is shown by 2,6-bis-(thiocarbamoylthiomethyl)pyridine [191]. Dithiocarbamic acids affect the biosynthesis of catecholamines [192] and hepatosine [193], cause immune responses when used with levamisole [194], and reduce cholesterol production in rat liver [195]. Tetraethylthiuram monosulfide is used in conjunction with salicylic acid in the treatment of leishmaniasis [196]. Fungal infections of the skin can be treated with zinc ethylenebis(dithiocarbamate) [197]. Dithiocarbamates are anticaries agents [198]. 3-Aminotetrahydro-1,3-thiazine-2,4-diones [199], produced from cyclic dithiocarbamic acids, are skin-protecting agents. Certain tetrahydro-β-carbolines containing a dithiocarbamic acid structure are effective in liver therapy [200].

5.4. Radioprotective Agents

Dithiocarbamic acid esters and other derivatives provide protection against γ-radiation [201–206]. The metabolism of some of these agents in mice has been studied [207]. Polymers, e.g., poly(vinyl chloride), that contain dithiocarbamic acid substituents are more radiation resistant than unsubstituted polymers [208].

5.5. Imaging Technology

Dithiocarbamic acids and their derivatives have many applications in photographic and recording materials [209–211].

Heat-sensitive copying materials contain, for example, tetramethylthiuram disulfide and zinc dithiocarbamates [212]. Light-sensitive photographic materials for high-contrast negatives and direct-positive photographic materials employ certain dithiocarbamates [213], [214].

Dithiocarbamates are used in color photography [215] and in electrophotographic materials [216]. Photopolymerizable printing compositions contain thiuram sulfides [217], and latent image developers contain zinc dithiocarbamates [218]. Developer compositions for electrolyte photography may contain small amounts of dimethyldithiocarbamates [219]. Dithiocarbamates are likewise used in the bleaching of photographic materials [220] and in photothermographic materials [221]. Thermodeveloping photographic materials contain metal derivatives of dithiocarbamic acid [222], [223].

Dialkyldithiocarbamates [224] or rhodanines [225] are employed in photosensitive resin compositions, and certain rhodanines are used in sensitizing dyes [226]. Photosensitive materials for high resolution may contain cyclic dithiocarbamic acid esters [227]. Solutions containing dithiocarbamic acid or its salts are used in the production of photographic relief images [228], [229]. Dialkyldithiocarbamic acid derivatives are used in the bleaching of silver halide-containing photographic materials [230]. Small amounts of dithiocarbamic acid derivatives increase the brilliance of photographic silver images [231]. Ammonium dithiocarbamate is a heat and moisture stabilizer for photographic emulsions [232]. Combinations of sulfinic acids and ammonium salts of dithiocarbamic acid, as well as thiuram disulfides, increase the sensitivity of photographic emulsions [233–238]. Certain dithiocarbamic acid derivatives increase the sensitivity of diazole compounds in diazotype printing [239]. Dialkyldithiocarbamic acid derivatives stabilize silver halide emulsions [240]. Gel formation in photopolymerization is prevented by dithiocarbamates [241], which produce positive prints with small amounts of silver halides [242]. Color fading in silver halide images can be prevented by treatment with a dithiocarbamate salt solution [243]. Color images are produced in direct-positive processes with the aid of dithiocarbamic acid derivatives [244]. Silver ions and a solution containing sodium *N*-methyldithiocarbamate [245] participate in the photocuring of high molecular mass substances containing amino or amido groups. Dithiocarbamates are used in the recovery of silver from photographic processing solutions [246].

5.6. Other Uses

Curing Agents. Heavy-metal salts of dibutyldithiocarbamic acid in epoxy resins improve adhesion properties and moisture resistance, and inhibit rust formation [247]. Treatment of halogen-containing elastomers with a dimercaptothiadiazole – dithiocarbamate mixture improves flow behavior and cure rates [248].

Separation of Heavy Metals. Dithiocarbamates precipitate heavy metals such as cadmium, nickel, and zinc from aqueous solution [249], [250]. Polydithiocarbamate resins remove heavy-metal ions from wastewater [251]. Dithiocarbamic acid derivatives are employed as flotation agents for copper, zinc, nickel, lead, and iron ores [252].

Complexation. Dithiocarbamic acid derivatives stabilize transition metals in high states of oxidation [253]. The resulting metal complexes have been the subject of electrochemical [254], crystallographic [255], thermochemical [256], and structural [257] studies.

Stabilizers for Polymers and Oils. Zinc dithiocarbamates improve the thermal stability of polymers, especially polyurethane elastomers [258]; combinations with sterically hindered phenols show synergistic stabilizing effects [259], [260]. Zinc dialkyldithiocarbamates are antioxidants [261]. Nickel dithiocarbamate inhibits the photodegradation of polyethylene [259], [262]. Dithiocarbamates improve the ozone resistance of printing plates [263] and the stability of photosensitive resins [264]. Protective effects are found in the radiofrequency range [265]. Certain metal derivatives serve as oil [266] and lubricant additives [267]. Aqueous synthetic resin dispersions containing tetramethylthiuram disulfide as a fungicide have improved storage stability [268]. Organopolysiloxane-based sealants used in the construction industry are protected from fungus attack by tetraalkylthiuram disulfide [269]. Biocides consisting of copper salts of alkylenebis(dithiocarbamates) and triphenyltin hydroxide considerably extend the life of underwater paints [270].

Analysis. Dithiocarbamic acids are useful in inorganic [271], [272] and other analyses [273], especially to determine trace amounts of heavy metals in organic and biological materials [186],

[274–276]; they can also be used as chelating agents in HPLC [277].

6. Toxicology and Occupational Health

The toxicity of dithiocarbamic acid derivatives [278–280] and oxidation products of the dithiocarbamates [281] has been investigated extensively. The biological activity of some dithiocarbamic acid derivatives is treated in [282]. The embryotoxicity of dithiocarbamates is being studied, with particular attention to the derivatives used in the rubber industry [283] and in pesticides [284]. The teratogenicity potential of such compounds [285] and their metabolites [286] has also been investigated. Mutagenicity studies of dithiocarbamic acid pesticides [287–289] and of products used in the rubber industry [290–292] have been reported. Cytological and genetic effects of ethylenebis(dithiocarbamates) used as fungicides have been investigated with the aid of *Allium cepa* [293]. Genotoxic effects have been observed for both synthetic elastomer additives (especially thiuram sulfides and dithiocarbamates) and pesticides [294].

Formation of Nitrosamines. During the vulcanization of rubber, dithiocarbamic acid derivatives used as accelerators form trace amounts of amines [295]. These amines react with nitrogen oxides from the air or with nitrosating ingredients of rubber compounds to form highly toxic nitrosamines [296]. The carcinogenic potential of these nitrosamines is being studied.

The TLV-TWAs and MAK values are 5 mg/m^3 for thiram (tetramethylthiuram disulfide) and 2 mg/m^3 for disulfiram (tetraethylthiuram disulfide).

1. Introduction

Diuretics are generally defined as substances that cause an increased excretion of urine. The name saluretic or salidiuretic refers to the stimulation of salt excretion caused by these substances. Since urine always contains inorganic salts and since the total concentration of ions (predominantly sodium, potassium, chloride, and hydrogencarbonate ions) is only slightly influenced by drugs, the terms diuretic and saluretic are often used synonymously.

In the recent literature, however, it has become customary to define saluretics as substances that directly stimulate the excretion of salts by inhibiting electrolyte reabsorption in the kidney tubules, sodium being the main cation and chloride being the main anion excreted. In this article, the term saluretic is used in this sense.

Physiological Basis of Diuretic Function. The smallest functional unit of the kidney is the nephron, which can be divided into four different sections: the glomerulus (a capillary filter), the proximal tubule, the loop of Henle, and the distal tubule, which terminates in the collecting duct. Blood plasma is filtered through the glomerular capillaries (approximately 180 L of plasma per day in an adult) and enters the proximal tubule as an ultrafiltrate. In the proximal tubule 50 – 60 % of the filtrate is reabsorbed. Apart from Na^+, Cl^-, HCO_3^-, and K^+ ions, many other substances, such as glucose and amino acids, are reabsorbed. Hydrogencarbonate reabsorption in this section of the nephron is inhibited primarily by carbonic anhydrase blockers.

Approximately 30 % of the glomerular filtrate is reabsorbed in the following loop of Henle, which is divided into an ascending and a descending limb. The thick ascending limb, in which electrolytes are transported through a water impermeable membrane, is especially important for diuretic activity. An active $Na^+ 2\,Cl^- K^+$ cotransport takes place, which is inhibited by loop diuretics.

Only ca. 10 % of the glomerular filtrate is reabsorbed in the distal tubule. Sodium and chloride ions are actively reabsorbed against a concentration gradient. Diuretics having thiazide-like activity inhibit ion transport in the early part of the distal tubule. In the late part of the distal tubule and in the collecting ducts, where final adjustments in the composition of urine occur, NaCl reabsorption is accompanied by secretion of potassium and hydrogen ions. This formal sodium – potassium exchange is prevented by potassium-retaining diuretics or aldosterone antagonists.

Potassium secretion in the late part of the distal tubules and in the collecting ducts is stimulated by an accelerated tubular flow rate and an increased delivery of sodium. Consequently, diuretics that act in an earlier part of the nephron cause increased potassium secretion.

Diuretics produce a loss of electrolytes and fluids; this induces compensation

10.1002/14356007.a09_029

phenomena, such as activation of the renin – angiotensin – aldosterone system. A long-term diuretic therapy, therefore, can result in a marked decline in the effect produced.

Fields of Application. Diuretics are administered when an increased excretion of extracellular fluids is desired. They are used to treat acute forms of edema, like cerebral and pulmonary edema, and to control chronic cardiac, hepatic, or renal edema or edema accompanying a toxic – allergic condition.

The discovery of the antihypertensive properties of saluretics in the early 1960s considerably broadened the scope of application of these drugs. Saluretics are especially important in the treatment of essential hypertension, which makes up approximately 80 % of all cases of hypertension. They are firmly established as being safe and reliable. Indeed, saluretics and β-adrenoceptor antagonists are the basic drugs used to treat high blood pressure and are used either alone or in combination with other antihypertensive medication, depending on the seriousness of the condition (→ Antihypertensives).

Historical Development. Until 1950, apart from plant extracts and the so-called osmotic diuretics, doctors had only two classes of substances at their disposal for the treatment of edema: the *xanthine derivatives* and related nitrogen heterocyclic compounds, primarily pyrimidine and triazine derivatives, and an extensive number of *organic mercurial compounds.* Typical examples of these groups are theophylline [*58-55-9*]

and mersalyl [*492-18-2*].

Mercurial compounds have been almost completely replaced by the sulfonamide saluretics, which are considerably better tolerated. As diuretics the xanthine drugs still on the market are not very potent; they are employed mainly because of their cardiotonic and bronchodilator activity (→ Antiasthmatic Agents, Chap. 2.2.).

After years of stagnation, diuretic research has received new impetus. Drugs like renal vasodilators (especially dopamine agonists like ibopamine [*66195-31-1*]; see also → Cardiac Glycosides and Synthetic Cardiotonic Drugs, Chap. 3.1.) [3], vasopressin antagonists [4], and the atrial natriuretic factor (ANF) and its derivatives [5] are currently being developed.

The most important diuretics currently used can be classified into three main groups, according to their site of action and mechanism of action: (1) carbonic anhydrase blockers, (2) saluretics, and (3) potassium-retaining diuretics.

2. Carbonic Anhydrase Blockers

The enzyme carbonic anhydrase catalyzes the hydration of carbon dioxide in tubular cells. Carbonic anhydrase inhibition results in a shortage of hydrogen ions and an increased excretion of sodium and hydrogencarbonate ions. This leads to alkalinization of urine, a fall in blood pH (hyperchloremic acidosis), and an increase in potassium excretion. However, the use of carbonic anhydrase inhibitors has declined. They are used mainly in the treatment of glaucoma and to some extent in epilepsy (→ Antiepileptics, Chap. 2.8.). As a result of the acidification effect, they are also employed as adjuvants in the treatment of alkalosis.

Acetazolamide [*59-66-5*], 2-acetylamino-1,3,4-thiadiazole-5-sulfonamide, $C_4H_6N_4O_3S_2$, M_r 222.2, the most important commercial preparation, was developed by Roblin and Clapp in 1950 [6]. It crystallizes from water in the form of colorless prisms, *mp* 268 – 270 °C (decomp.); it is sparingly soluble in cold water and readily soluble in 1 N sodium carbonate solution.

Acetazolamide is preferably administered orally in daily doses of up to 1.0 g. The diuretic

effect starts ca. 2 h after administration. After several days of treatment, however, the diuretic effect declines steadily because of increasing acidosis. The drug should then be discontinued for ca. 4 d, but it regains full activity as soon as normalization of plasma pH occurs.

The high potassium excretion is the most serious side effect caused by acetazolamide. Indeed, it is imperative that patients subjected to long-term medication be given potassium supplements (fruit juices, bananas, KCl preparations) to prevent potassium deficiency symptoms like paresthesia, muscle cramps, and drowsiness.

Synthesis. Oxidative chlorination of 2-acetylamino-5-mercapto-1,3,4-thiadiazole or its *S*-benzyl or *S*-acyl derivatives to the corresponding sulfonyl chlorides followed by reaction with ammonia [7] has proved to be an optimal method for the synthesis of acetazolamide.

Trade Names. Diamox (Cyanamid-Novalis), Glaupax (Dispersa).

3. Saluretics

Saluretics are currently the most important drugs used in the treatment of edema. They have also become increasingly important in the treatment of hypertension (→ Antihypertensives). Their structure differs from that of carbonic anhydrase blockers in that the heterocyclic ring substituted with the sulfonamide group is replaced by a phenyl moiety. They have a very weak inhibitory effect on carbonic anhydrase and, consequently, only a small influence on the excretion of HCO_3^- in the urine. Sodium chloride excretion is predominantly enhanced. There are marked differences within the group with respect to potency, efficacy, duration of action, and potassium excretion.

3.1. Thiazide-like Diuretics

Thiazide-like saluretics inhibit sodium reabsorption only in a very limited area of the nephron, namely the cortical segment of the loop of Henle and the early part of the distal tubule. In addition, a site of action in the proximal tubule has been found. The efficacy of these drugs is not very high; the duration of action is prolonged. They are especially suitable in the treatment of hypertension, either alone or in combination with other drugs.

3.1.1. Benzothiadiazine Derivatives

Chlorothiazide. This preparation, developed by Novello and Sprague [8], was the very first saluretic on the market. Chlorothiazide [*58-94-6*], 6-chloro-7-sulfamoyl-2*H*-1,2,4-benzothiadiazine 1,1-dioxide, $C_7H_6ClN_3O_4S_2$, M_r 295.7, decomposes at 345 °C. Solubility in water is ca. 0.04 % at pH 4 and 0.15 % at pH 7. The compound is readily soluble in aqueous alkalies, in which it is slowly hydrolyzed with ring opening.

Chlorothiazide possesses one tenth of the carbonic anhydrase inhibitory effect shown by acetazolamide. In oral doses of 1 – 2 g, the drug evokes a copious salidiuresis, which reaches a maximum after 3 – 4 h. Even after long-term administration, it remains fully effective.

Synthesis. Chlorothiazide is synthesized starting from 3-chloroaniline. This compound is converted to the corresponding 4,6-disulfonamide in two steps by reaction with chlorosulfuric acid and ammonia; ring closure is effected with formic acid [9].

Trade Names. Chlotride, Saluric, Diuril, Diupres (all Merck Sharp & Dohme).

Hydrochlorothiazide. Chlorothiazide was on the market only a year when de Stevens [10] in Switzerland developed hydrochlorothiazide. This new drug proved to be of considerable therapeutic importance.

Hydrochlorothiazide [*58-93-5*], 6-chloro-3,4-dihydro-7-sulfamoyl-2*H*-1,2,4-benzothiadiazine 1,1-dioxide, $C_7H_8ClN_3O_4S_2$, M_r 297.7, crystallizes from aqueous ethanol as colorless prisms, *mp* 274 – 275 °C. It is soluble in 1 N sodium carbonate solution, in which it is gradually hydrolyzed, even at room temperature, to give the disulfonamide and formaldehyde.

Hydrochlorothiazide is 15 – 20 times more potent than chlorothiazide and exerts an even smaller inhibitory effect on carbonic anhydrase [11]. It is much better tolerated than chlorothiazide. Combination preparations with potassium-retaining diuretics (triamterene and amiloride, see Section 4.2) are also on the market.

Synthesis. There are several methods available for the production of hydrochlorothiazide. Chlorothiazide can be reduced electrolytically or with sodium borohydride [12] or catalytically [13]. On the other hand, 3-chloro-4,6-disulfamoylaniline can be cyclized with formaldehyde [14] to give hydrochlorothiazide.

Trade Names. Di-Chlotride, Hydro-Diuril, Hydro-Saluric (all Merck Sharp & Dohme); Esidrix (Ciba); Oretic (Abbott); Dytide H (combination with triamterene, Röhm Pharma); Moduretic (combination with amiloride, Merck Sharp & Dohme).

Hydrochlorothiazide Analogues. Substituents in the 3-position or in the 2- and 3-positions can substantially increase potency. However, replacement of the chlorine atom by a trifluoromethyl group has almost no influence on potency. Some well-known analogues are listed in Table 1. Despite the large number of newer thiazine dioxide derivatives, hydrochlorothiazide remains the most important thiazide-type drug on the market. In their biological action, these chemical analogues differ from hydrochlorothiazide mainly by their lower threshold dose and, consequently, the therapeutic dose (potency); the maximum saluretic effect (efficacy), however, is not larger. The most potent compound of this series is cyclopenthiazide, which was put on the market in 1961. Its threshold dose in humans is 0.125 mg. The maximum response is obtained in therapeutic doses as low as 1.0 mg [22].

3.1.2. Other Saluretics with Thiazide-like Activity

Table 2 lists some other saluretics with thiazide-like activity. With the exception of tienilic acid (ticrynafen) all these compounds are sulfonamide derivatives. Tienilic acid differs from the other saluretics in that it causes an increased excretion of uric acid (uricosuric activity). However, this drug has been removed from the market in most countries because it is believed to be connected with hepatotoxic effects [32].

3.2. Loop Saluretics

Loop diuretics, also known as high-ceiling diuretics, act by inhibiting reabsorption of sodium chloride in a more extensive area of the nephron than the thiazide-like saluretics. They primarily act in the medullary segment of the loop of Henle and to a lesser extent in the proximal tubule. Their efficacy is much higher than that of the thiazide-like saluretics. A further characteristic is the shorter duration of action.

3.2.1. Furosemide

Furosemide [*54-31-9*], frusemide, 4-chloro-*N*-(2-furylmethyl)-5-sulfamoyl anthranilic acid, $C_{12}H_{11}ClN_2O_5S$, M_r 330.8, was the first high-ceiling diuretic on the market and is still the most important product in this group. It is sparingly soluble in water and crystallizes from ethanol or nitromethane as colorless prisms, which decompose at 208 °C. The sodium salt can be recrystallized from water; the solubility of the salt in water at room temperature is 6 %.

Furosemide was discovered in 1959 [33] and was put on the market in the Federal Republic of Germany in March 1964. A free carboxyl group gives it a strong hydrophilic character, which causes rapid onset of diuresis (30 – 60 min after oral administration, a few minutes after intravenous injection) and rapid elimination. The efficacy of this drug is extremely high. With respect to the maximum natriuresis produced, furosemide is 8 – 10 times more effective than

Table 1. Hydrochlorothiazide analogues

X	R^1	R^2	*Generic name* Trade name	CAS registry number	Therapeutic dose, mg
$-CF_3$	H	H	*hydroflumethiazide* [15] Naclex (Glaxo)	[*135-09-1*]	25 – 150
Cl	H	isobutyl	*buthiazide, thiabutazide* Saltucin (Boehringer Mannheim)	[*2043-38-1*]	20 – 100
$-CF_3$	H	benzyl	*bendroflumethiazide* [15] Naturetin (Squibb)	[*73-48-3*]	5 – 20

Cl	$-CH_3$	$-CH_2Cl$	*methylclothiazide* [18] Enduron (Abbot)	[*135-07-9*]	2 – 10
Cl	$-CH_3$	$-CH_2SCH_2CF_3$	*polythiazide* [19] Renese, Drenusil (Pfizer)	[*346-18-9*]	1 – 5
Cl	H		*cyclothiazide* [20] Anhydron (Lilly)	[*2259-96-3*]	1 – 2
Cl	H		*cyclopenthiazide* [21] Navidrex (Ciba)	[*742-20-1*]	0.5 – 1

the thiazides [34]. Hence, the therapeutic efficacy of furosemide is extremely high, especially as the drug shows practically no toxic side effects.

Synthesis. Furosemide is produced by treatment of 2,4-dichloro-5-sulfamoylbenzoic acid with excess furfurylamine in the absence of solvent at 120 – 130 °C [33], [35].

Trade Names. Lasix, Lasilix, Seguril (Hoechst).

3.2.2. Other Loop Diuretics

As shown in Table 3, loop diuretics are derived from completely different classes of chemical substances. The two sulfonamide derivatives, *bumetanide* [36] and *piretanide* [37], have a pharmacological activity profile very similar to that of furosemide, but are much more potent. Piretanide has proved to be very useful in the treatment of hypertension. *Ethacrynic acid* [38] is 5 times more effective than the thiazides; however, it has not attained particular importance, presumably because of side effects. The pyrazolone derivative *muzolimine* [39] combines the saluretic pattern of loop diuretics with a prolonged duration of action, whereas *etozolin* [40] shows reduced side effects on glucose metabolism. In 1987, shortly after the introduction of muzolimine onto the market in Germany, it was withdrawn for toxicological (polyneuropathy) reasons.

4. Potassium-Retaining Diuretics

4.1. Aldosterone Antagonists

Spironolactone [*52-01-7*] [41] and potassium canrenoate [42] [Aldactone (Searle, Boehringer Mannheim), Osyrol (Hoechst), Soldactone (Searle)] are used as aldosterone antagonists. Aldosterone stimulates sodium and water reabsorption in the late part of the distal tubule and in the collecting ducts.

Aldosterone

Table 2. Other saluretics with thiazide-like activity

Class of substance Formula	R^1	R^2	*Generic name* Trade name	CAS registry number

	H		*clopamide* [27] Brinaldix (Sandoz)	[*636-54-4*]
	H		*indapamide* [28] Natrilix (Servier, Itherapia)	[*26807-65-8*]
	H		*tripamide* [26] Normonal (Eisai)	[*7308-48-2*]
Others				
			*chlorthalidone* [30] Hygroton (Ciba-Geigy)	[*77-36-1*]
			*ticrynafen* [31] Diflurex (Crephar)	[*40180-04-9*]

Aldosterone antagonists, on the other hand, enhance sodium excretion and diminish potassium secretion. After administration of these compounds only about 2 % of the filtered sodium is excreted. Aldosterone antagonists act only in the presence of aldosterone. The response to these drugs is slow in onset. The complete saluretic activity will be reached only after several days of treatment. Spironolactone (for details on synthesis, see [42]) is insoluble in water, but potassium canrenoate is water-soluble and hence can be given by parenteral administration. Both spironolactone and canrenoate are rapidly converted to the active metabolite canrenone, which has a half-life of ca. 20 h.

Sipronolactone

Potassium canrenoate

Canrenone

Aldosterone antagonists are always indicated in the treatment of edema accompanied by hyperaldosteronism. The most dangerous side effect is hyperkalemia.

4.2. Other Potassium-Retaining Diuretics

Triamterene and amiloride also decrease the excretion of potassium. However, their mechanism of action differs from that of spironolactone. They do not inhibit aldosterone; modern electrophysiological methods indicate that they block the luminal sodium binding site at the sodium – potassium exchange mechanism in the late part of the distal tubule (see also → Antihypertensives, Chap. 2.2.). Triamterene and amiloride are used mainly in combination with hydrochlorothiazide and other saluretics (see Section 3.1.1) in order to prevent diuretic induced hypokalemia.

Table 3. Loop diuretics

Formula	*Generic name* Trade name	CAS registry number
	*bumetanide* Burinex (Leo)	[*28395-03-1*]
	piretanide Arelix (Hoechst)	[*55837-27-9*]
	*muzolimine* Edrul (Bayer, Zyma)	[*55294-15-0*]
	*etozolin* Elkapin (Gödecke)	[*73-09-6*]
	*etacrynic acid* Edecrin, Hydromedin (Merck Sharp & Dohme)	[*58-54-8*]

Triamterene [*396-01-0*], $C_{12}H_{11}N_7$, M_r 253.3, *mp* 316 °C, is obtained by condensation of 2,4,6-triamino-5-nitrosopyrimidine with benzyl cyanide [43].

Trade Names. Dyrenium, Triamterene (Smith, Kline & French); Teriam (Roussel); Jatropur (Röhm Pharma); Dytide H (combination with hydrochlorothiazide, Röhm Pharma).

Amiloride [*2609-46-3*], $C_6H_9Cl_2N_7O$, M_r 266.2, *mp* 285 – 288 °C (decomp.), is synthesized as follows: Methyl 3-aminopyrazine-2-carboxylate is chlorinated with sulfuryl chloride to methyl 3-amino-5,6-dichloropyrazine-2-carboxylate; treatment with ammonia gives methyl 3,5-diamino-6-chloropyrazine-2-carboxylate, which is converted to amiloride by reaction with guanidine [44].

Trade Names. Colectril, Midamor; Moduretic (combination with hydrochlorothiazide); all Merck Sharp & Dohme.

5. Aquaretics

Aquaretics are agents which selectively increase the renal excretion of osmotically free water without major changes in electrolyte homeostasis. They dilute urine to an osmolality distinctly below plasma osmolality values and produce a hypotonic urine. Since vasopressin is the primary hormonal regulator of total body water, the discovery of diuretic vasopressin analogues has initiated interest in vasopressin receptor antagonists as potential specific water diuretics [45]. On the basis of the mechanism of action and chemical structure, one can differentiate three main types of aquaretics:

1) Vasopressin-analogous V2 receptor antagonists
2) Nonpeptide V2 receptor antagonists such as OPC-31260
3) Nonpeptide κ-opioid receptor antagonists

The benzazepine derivative OPC-31260, 5-dimethylamino-1-{4-(2-methylbenzoylamino)benzoyl}-2,3,4,5-tetrahydro-1*H*-benzazepine, is a selective nonpeptide V2 receptor antagonist [46]. OPC-31260 inhibits arginine vasopressin binding to V1 and V2 receptors in a competitive manner, whereby it is 100 times more selective for V2 than for V1 receptors. Furthermore, OPC-31260 does not have partial agonistic activity, and after oral administration to rats, causes a dose-dependent diuretic effect, significantly lowering the osmolality of the urine. OPC-31260 has entered phase II studies.

6. Adenosine A1 Receptor Antagonists

Adenosine A1 receptor antagonists are a relatively new class of compounds which may have therapeutic potential in treatment of edematous states of different origin and in acute renal failure (ARF). Adenosine, a degradation product of ATP, plays a significant role in normal and ischemic kidney function [47]. Adenosine is a vasodilator in most vascular beds but acts as a vasoconstrictor in the kidney. In the kidney, adenosine A1 receptors are expressed in the renal vasculature, juxtaglomerular cells, in proximal tubules, the thick ascending limb of Henle's loop and in the papillary collecting duct. Adenosine vasoconstricts preglomerular vessels in the kidney, while vasodilating efferent arterioles. Thus adenosine has been shown to decrease glomerular filtration rate (GFR) and renal blood flow (RBF) by means of A1-receptor-mediated renal afferent arteriolar vasoconstriction and A2-receptor-mediated efferent arteriolar vasodilation. Furthermore, adenosine modulates tubular handling of electrolytes as well as tubuloglomerular feedback (TGF) and inhibits

renin release. Adenosine also seems to be involved in ischemia-induced ARF, renovascular hypertension, and in various nephrotoxic drug reactions.

Theophylline, a nonselective adenosine receptor antagonist, exerted therapeutic effects in various animal models and in contrast medium-induced renal insufficiency in humans. Recently developed selective adenosine A1 receptor antagonists CVT-124 (1,3-dipropyl-8-[2-(5,6-epoxy)norbornyl]xanthine, KW-3902 [8-(noradamantan-3-yl)-1,3-dipropylxanthine] and FK-453 {(+)-R-1-[(E)-3-(2-phenylpyrazolo[1,5-a]pyridin-3-yl) acrylol]-2-piperidine} have been described in preclinical studies as potent proximally acting diuretic agents with therapeutic efficacy in ischemia-induced ARF and in renal insufficiency provoked by nephrotoxic drugs such as cisplatin, gentamicin, and cephaloridine [48]. Clinical development status of these agents is Phase I/II. Currently, experimental and clinical data strongly support the hypothesis that blockage of the adenosine A1 receptors may be a new therapeutic principle in renal insufficiency.

1. Introduction

Ink, especially ballpoint ink, and pencil leads are the main drawing and writing media today. Charcoal, chalk, and crayons, although less important, are widely used.

History. Cave paintings of the ice age are considered to be the oldest documentation of human ingenuity, representing the first use of drawing materials. A piece of flint or a stone ax, the first writing tool, was used to scratch pictures on the walls of caves, pictures that were then painted with colored earth. Stone remained the most important writing surface for a long time. Even after the appearance of hieroglyphics next to the painted pictures and signs, stone and slate pencils continued to be the most common and long-lasting writing utensils.

Later, the flint and ax were supplemented by the chisel, for rough writing, and the gouge, for fine writing. In fact, until the beginning of the twentieth century, children learned to write with a slate and a slate pencil. However, clay tablets are easier to write on and also easier to transport. The writing was scratched into the soft, plastic surface, and the clay was then fired. Similarly, wax tablets, employed by Mediterranean traders, are light and easy to write on [5], [6]. The slate pencil was especially suitable for inscribing wax plates.

Even in early times, in addition to stone, metal, clay, and wax, thin rolls were available for writing. The Aztecs used fig leaves, and as far back as 3000 B.C., Egyptians pioneered the use of papyrus, which they prepared from the pith of the papyrus plant. Papyrus was employed until the ninth century A.D. [6], and a reed was used to write on papyrus. India ink is the oldest writing and drawing medium. As long ago as 2600 B.C., India ink sticks were prepared in China from lampblack and animal glue, and used for both writing and drawing. When rubbed with water, the sticks gave an aqueous dispersion of carbon – the basis for preparing India ink even today. The glue served as the protective colloid.

Parchment was discovered in Asia Minor around 200 B.C. Depilated, untanned goat- or calfskin provided the starting material. Parchment was used until the Middle Ages. Precious manuscripts still bear witness to the fine art of medieval manuscript writing [5], [7].

Tsai Lun discovered paper in 105 A.D. in China. However, this knowledge did not reach Europe until the eleventh century, at which time

10.1002/14356007.a09_037

the use of India ink and other inks for writing spread rapidly.

Pencils. In ancient times, CATULLUS and PLINY mentioned the use of graphite (Greek: *graphein*, to write) or lead disks to draw lines. The so-called silver pencil, an alloy of tin and lead, was used as a drawing instrument from the twelfth century on.

In the sixteenth century, CONRAD GESNER described graphite stick-shaped leads, which originated solely in England, and which were later protected by cartridges from breakage and abrasion. Deposits of very pure sheet graphite (later a crown monopoly) were found in Borrowdale, England, in 1564. Over 200 years later, in 1782, the chemist C. W. SCHEELE proved that graphite is hexagonal carbon, not lead or molybdenite. However, the term lead pencil was by that time firmly entrenched in the language. The manual production of wood-encased graphite leads began in Nürnberg, Germany, around 1662. In 1794, NICOLAS JACQUES CONTÉ, in France, ground graphite, mixed it with clay as a binding agent, and fired the mixture at ca. 1000 °C to obtain preformed sticks of ceramic leads. These showed three substantial improvements: (1) higher strength, preventing breakage during writing, (2) variable hardness achieved by changing the ratio of graphite to clay, and (3) more efficient utilization of graphite.

Pens. The Chinese used a fine hair brush to write on paper. For centuries, bird feathers, especially goose quills, were the instrument of choice for writing with ink. Pen nibs were made from copper, iron, and brass as early as the sixteenth century. In 1798, ALOIS SENEFELDER, the inventor of lithography, produced the first nib made from hardened steel [8], [9].

The Leipzig engineer SCHELLER is said to have constructed a fountain pen in 1781, and L. E. WATERMAN invented a fountain pen with a vulcanized rubber reservoir in 1883. Since 1887, generations of German students have learned writing and arithmetic while using Soennecken pens. In 1889, GUSTAV PICKHARDT patented a fountain pen consisting of a glass tube drawn out to a point at one end, a holder for the nib, and a wick made from a capillary fabric that transported the ink [10].

Ink. Progress in writing was closely connected with the development of India ink and other inks. The first ink was made by rubbing soot or a colored pigment such as cinnabar with water-soluble binding agents, e.g., glue or gum arabic. Pieces of solid India ink were rubbed against a stone with water to form a writing liquid, which could then be applied with a brush [9].

A few inks in use today were employed before the birth of Christ. For example, the bones of cattle were boiled to give a brew that, when mixed with iron vitriol and thickened, darkened on exposure to light and could be used as ink.

The Middle Ages brought forth recipes for iron – gallic inks that contained aqueous extracts of nut gall, iron vitriol, and gum arabic [11]. The first iron – gallic inks contained the actual ink dye – iron oxides of tannic and gallic acids – suspended in the liquid. The binding agent, gum arabic, was responsible for keeping the darkly colored iron salts suspended in the liquid and binding them to the surface of the paper.

AUGUST LEONHARDI's patent, in 1856, describing the production of so-called alizarin ink, was a breakthrough in ink chemistry. The innovation was the addition of a solution of iron(II) sulfate and indigo to the aqueous extract of Aleppo gall to produce a clear, filterable liquid containing dissolved iron(II) gallate. Conversion to the iron(III) salt by atmospheric oxygen gave rise to the actual ink dye only on the paper itself (this is also the reason for the sludge present in inkwells until the end of the nineteenth and beginning of the twentieth centuries). Another dye had to be present to make the ink visible immediately, and an extract of madder root, which contains alizarin, was employed for this purpose [12].

A formulation for indelible ink that met official German regulations in 1888 consisted of

23.4 g tannic acid
7.7 g gallic acid
30.0 g iron(II) sulfate
10.0 g gum arabic
10.0 g hydrochloric acid (25 wt %)
1.0 g phenol

diluted to 1 L with water. As early as 1890, the Leonardi company in Dresden produced 0.5×10^6 kg of ink annually [12].

Ballpoint Pens. Ballpoint pens were mass-produced in the United States in the 1940s and

introduced to Europe during World War II. However, pens having a ball instead of a nib to transfer ink or colored paste had been patented earlier [13]. Jose Biro, who has ca. 700 patents to his name, is largely responsible for the further development of ballpoint pens.

Chalk and Crayons. The simplest and one of the oldest writing materials is charcoal. Natural red iron oxide together with clay minerals was used as ruddle or bole chalk (fifteenth and sixteenth centuries), a forerunner of the pastels of the eighteenth century. Lumps of naturally occurring chalk were formed into sticks and used as white drawing chalk. Gray slate completed the palette of naturally occurring materials.

Wax is one of the oldest drawing materials. In ancient Roman wall and panel paintings, a wax drawing technique – encaustic, which employs melted wax – was used. These encaustic waxes were presumably formed into sticks, which were the forerunners of wax crayons.

2. Pencils

Today, a pencil refers to a dry writing instrument, usually 178 mm long, made from wood, metal, plastic, etc., with a sharpened, homogeneous graphite lead at its center.

2.1. Chemical Composition

A lead consists of several components.

Dye	graphite [*7782-42-5*], organic and inorganic pigments, triphenylmethane dyes
Binding agent	aluminum silicates (clays), plastics, methylcellulose [*9004-67-5*], lignin
Additive	fats, wax mixtures
Filler	kaolin [*1332-58-7*], talc [*14807-96-6*]

The binding agents and fillers function as the supporting framework of the lead in which the graphite and pigments are deposited. Both the nature of the binding agents and the ratio of the components determine the structure and hardness of the lead; the pigment determines the intensity of color. The pore volume of the lead is filled by dipping it in a hot fat – wax mixture, which decreases friction during writing. The choice of hard or soft fats – waxes allows some control over the degree of hardness. In addition, the adhesiveness, breaking strength, and color intensity of the lead can be increased in this way. The clay content varies from 15 wt % in the softest lead to ca. 60 wt % in the hardest. A mixture of about 2 parts of graphite and 1 part of clay gives the usual HB or 2 1/2 degrees of hardness.

2.2. Writing Properties

The quality of a lead is determined by its hardness, breaking strength, sliding ability, covering power, color intensity or blackness, brightness, light fastness, and erasability.

The hardness is a measure of the abrasion resistance of the lead. The Castell degrees of hardness have existed since 1910. This scale is abbreviated by using the first letters of the traditional English markings: B = black/soft, HB = medium, F = firm, and H = hard. Today, the scale encompasses 17 grades of hardness: 8 B – B, HB, F, H – 7 H. A same scale of hardness is being compiled for the ISO standards. The hardness scale in use in the United States employs only numbers, but the most important grades in the two scales have a one-to-one relationship.

3 B	2 B	B	HB	F	H	2 H	3 H	4 H
1	1 1/2	2	2 1/2	3	3 1/2	4	4 1/2	5

The breaking strength and sliding ability, opposing factors, are largely dependent on the proportion of binder to graphite.

On magnification, a pencil line is seen to be not an exact line but rather a collection of lead particles scraped off by the rough surface of the paper. The covering power and color intensity of a pencil line are determined by the adhesiveness, the rubbing off of the lead, and the intensity of the dyes.

2.3. Production

Graphite Leads. In the classical procedure, the starting materials – ground natural graphite and very fine clay – are first freed from sand,

oversized material, and impurities. The microcrystalline structure of graphite must be retained during grinding. The moistened mixture (15 wt % moisture) is homogenized in kneading machines and rolling mills, and subsequently extruded, cut, and dried. The leads are then fired in furnaces, similar to those used in ceramics, at 950 – 1200 °C. Although the graphite is not structurally changed, the clay sinters, releasing water to form a hard, firm structure. After firing, the lead is dipped into a hot fat – wax mixture and then either enclosed in a protective covering, usually wood, or used loose in mechanical pencils.

Polymerized Graphite Leads. Polymer leads contain, for example, a synthetic thermoplastic [14] or lignin [15] rather than clay. As in the classical procedure, graphite is mixed with the binder during grinding. After homogenization, the mixture is extruded into leads. The plastic pyrolyzes in the subsequent firing to produce a carbon skeleton, which assumes the function of the clay framework but far surpasses the breaking strength and elasticity of conventional leads. Polymer leads are used to prepare fine refills with diameters of 0.3, 0.5, 0.7, and 0.9 mm. The leads are impregnated with a fat – wax mixture, and the fat is then removed from the lead surface. Thus, they can be used as loose leads in mechanical pencils. The principal advantage of these is that they no longer have to be sharpened. These intensely colored leads, which possess superior breaking strength and sliding ability, can still be erased completely.

Colored Leads. Both the composition and the production of colored leads differ greatly from those of graphite leads. Because the pigments are not resistant to high firing temperatures, clay or carbon cannot be used as binding agents. The binding agent must be a substance that is capable of swelling in water, such as methylcellulose, a cellulose derivative; a synthetic thermoplastic; or a substance, such as cellulose nitrate or ethylcellulose, that dissolves in an organic solvent and hardens as a result of the evaporation of the solvent at moderate heat. The pigments are homogenized with the binders, fillers (e.g., kaolin, powdered talc, chalk), additives, and fungicides by kneading and rolling. The mixture is subsequently passed through an extruder and dried below 100 °C. The extruded and dried leads are dipped into a fat – wax bath. Fat improves the consistency, sliding ability, and color intensity; the lead is wipe-resistant and nonfading, and can have either bright or pastel color (e.g., Polychromos). The resistance to light depends primarily on the quality of the pigment. Binding agents that are insoluble in water are not attacked by atmospheric humidity.

In addition to these oily, chalky leads, there are hard emulsion leads that contain fat and emulsifiers in the initial mixture and therefore do not have to be treated afterward. These leads may be blended like watercolors and can be used with water for painting (traces remain).

Indelible Leads. Indelible pencils (copying pencils), which allow duplication in the copying press, are produced much like colored pencils. The dyes, however, are water soluble and usually organic, e.g., triphenylmethane dyes. Indelible pencils and colored indelible pencils are not erasable. The ink dye penetrates the fibrous tissue of the paper through the moisture on the surface. Black indelible pencils contain up to 60 % graphite and methyl violet; consequently, they write black and copy violet. The colored leads do not contain graphite but rather water-soluble ink dyes. Indelible pencils have been almost entirely replaced by indelible ballpoint pens.

Wooden Pencils. California cedar (*Libocedrus decurrens*) is the preferred wood for pencils. In addition, alder, linden, fir, poplar, and some tropical woods (e.g., jelutong) are suitable. The wood is cut into boards, called *slats*, half the thickness of a pencil and then impregnated to improve the cutting quality and standardize the shade. The slats, most commonly 184 × 70 × 5 mm, must be knotless, straight, free from tension, dry, and soft enough to be sharpened without splintering. Five to ten half-grooves are cut into the slats on an automatic pencil assembly belt. After insertion of the lead and gluing of two slats to enclose the lead, the glued slats are dried under pressure. They are then cut into hexagon, oval, or round pencils and planed to size. Subsequently, the raw pencils are sent to the polishing room, where up to nine layers of varnish are applied. Labeling is carried out by foil-stamping, direct printing, or offset printing. Despite intensive automation, more than 30 steps are neces-

sary to convert lead and wooden slat into a pencil (Fig. 1)

Figure 1. Pencil production
A) leads; B) seasoned, impregnated cedar slat; C) grooved slat; D) grooved slat with leads inserted; E) lead sandwich; F) final shaping; G) unfinished pencils; H) pencils

Pencils produced by plastic coextrusion could not match the high quality of wooden pencils, and were not accepted by the consumer.

3. Ink

The inks described in this chapter are writing and drawing liquids having a variety of compositions and intended for a variety of uses. There are two basic types of inks, one that contains fine carbon or a colored pigment suspended in water with the aid of a binder (e.g., India ink), which has tended to be used in drawing, and one that contains water-soluble dyes (e.g., fountain pen ink), which has tended to be used for writing. Photographs courtesy of A.W. Faber-Castell GmbH & Co.

3.1. Drawing Ink

Liquid drawing inks, for example, *India ink,* have been produced and sold commercially since the turn of the century. These inks consist of a suspension of carbon black in a colloidal solution of shellac soap, which is stabilized with glue, the protective colloid, and provided with a suitable preservative. Poly(acrylic acid ester) can be used in place of the shellac soap. Carbon black [*1333-86-4*] is the best form of carbon (→ Carbon, Chap. 6.). The shellac is converted into a soap by means of a weak base – borax, ammonia, morpholine, or ammonium hydrogen carbonate.

The best protective colloids are the nongelling animal glues; however, poly(vinyl alcohol), methylcellulose, hydroxyethylcellulose, carboxymethylcellulose, other high molecular mass, water-insoluble polymers, and surfactants are also used. Formerly, the most common preservative was phenol, but this is being increasingly replaced by less toxic compounds.

The carbon black is suspended in a concentrated solution of the other ingredients in roller mills, ball mills, or homogenizers. The ink is allowed to stand several weeks in wood or plastic containers, or it is centrifuged, before being put into bottles. Quality standards for drawing inks exist in the United States, Great Britain (BS 2490), Canada, Israel, etc., and usually concern composition and stability with respect to light and water.

When the ink dries, the hardened shellac makes a water-insoluble, nonfading line. Generally speaking, India ink should have excel-

lent covering power and produce lines of uniform width and a sharp edge. Ink used in automatic drawing devices should flow quickly and smoothly.

The high concentration of pigment and binding agents tends to cause ink to dry on the point of the pen. This tendency can be reduced by the use of moisturizers, but then the ink also drys more slowly after application.

Colored inks may be either opaque or transparent. Opaque inks contain organic or inorganic pigments, whereas transparent inks contain ordinary water-soluble dyes of the sort used in writing inks. Otherwise, colored inks are made much like India ink and contain similar substances. Exceptions are the inks used on transparent plastic films, such as those employed by cartographers. Here the writing surface is hydrophobic and nonabsorbing. These inks are made with solvents that etch the surface of the plastic film; the etching promotes adhesion. In addition, these inks must be resistant to water, gasoline, and alcohol.

3.2. Indelible Ink

Indelible inks are iron – gallic inks containing specified amounts of tanning agents and iron sulfate. They are used primarily to sign notarized contracts and important documents. Today, the quantity of indelible inks purchased is relatively small.

3.3. Ink for Fountain Pens

3.3.1. Blue-Black Ink

Ink for fountain pens should flow well; it contains less iron and tannic acid than indelible ink but more water-soluble dyes. Originally, these inks had a bright blue color, on paper, which darkened with time when exposed to light. They are often called blue-black inks. An example of their composition is

2.0 g tannic acid
4.0 g gallic acid
7.5 g other tanning agents
5.7 g iron(II) sulfate
1.2 g sulfuric acid (94 – 95 wt %)
7.0 g ink blue R
1.5 g amino blue A
3.0 g gum arabic
1.5 g preservatives

diluted to 1 kg with water.

A sketch depicting the construction of a modern cartridge fountain pen is shown in Figure 2. A photograph of a modern fountain pen is shown as Figure 3 A, along with other types of pens that use ink.

Figure 2. Cartridge pen:

Figure 3. Pens:
A) modern fountain pen; B) ballpoint pen; C) ballpoint ink pen; D) fiber-tip pen
photographs courtesy of Pelikan Aktiengesellschaft

3.3.2. Colored Ink

The inks used most often today for fountain pens are colored inks. These write better than iron – gallic inks. The addition of a moisturizer (glycerin, glycol, or sorbitol) keeps the ink liquid in the pen and at the nib, even if the pen has been left open. A triacylmethane dye is the basis for the most common blue ink.

Ink blue (Acid Blue 93, C.I. 42780), patented by A. W. Hofmann in 1858, and its modifications are the most frequently used ink dyes. Ink containing this dye has the advantage of being completely removable (i.e., erasable) with sulfite solution, which was largely responsible for the increased use of fountain pens, especially among students. Young consumers today increasingly employ inks having a color other than blue.

An example of the composition of a blue ink is

17.0 g moisturizer
2.5 g sulfuric acid (94 – 95 wt %)
5.0 g ink blue
0.1 g surfactive agents
0.5 g preservatives

diluted to 1 kg with water.

These inks are produced easily. The moisturizer, usually glycerol or sorbitol, is diluted with water; sulfuric acid added; and the dye stirred into the mixture. The resulting liquid is heated to 80 °C and stirred until the dye is completely dissolved. After cooling, the surfactive agents and preservatives are added.

If preservatives are not used, molds tend to grow in both iron – gallic and colored inks; these can clogs fountain pens. Formerly, most inks were preserved with phenol; however, today only preservatives that comply with food laws are used.

3.4. Ballpoint Pens and Inks

The functional core of a ballpoint pen (Fig. 3 B) is the refill which, in the final analysis, is res-

Figure 4. Ballpoint pen:
a) push button; b) switching mechanism; c) top part with clip; d) refill; e) compression spring; f) front; g) point; h) ball

ponsible for the quality of the pen. In the Federal Republic of Germany, a quality refill must satisfy the requirements stipulated in DIN 16554. The main components of a refill are the ball, the ball bed, the cartridge that contains the paste, and the plug responsible for leakproofing.

The materials used to make a ballpoint refill are usually tungsten carbide or sapphire for the ball and brass, stainless steel, plastic, or a copper – nickel alloy for the bed. The cartridge is generally made from plastic or brass. The refill is made leakproof by means of a plastic foam plug that is permeable to air. The so-called large-capacity refills have a plug made from soft, pasty hydrocarbons or silicone grease that floats on the surface of the colored paste and moves along with it. Ballpoints, like other pens, depend on capillarity to function (see Fig. 4). The rolling ball transfers a film of color from its surface to the paper; the ball itself is constantly wetted by the paste in the cartridge. A uniform wetting of the surface of the ball is made possible by a narrow gap between the ball and the bed, and by distributing chanels in the bed. The surface tension and viscosity of the writing paste must be suitable for the pen. Many pastes are characterized by a viscosity of 10 – 20 Pa s and a surface tension of ca. 40 mN/m at 20 °C.

A dye concentration up to 40 % ensures intense color. Dyes digested in oleic acid or acid resins, or metal – complex dyes soluble in organic solvents (e.g., phthalocyanine dyes) are suitable. Metal – complex dyes make the paste resistant to light and chemicals (as required by DIN 16554). The flowability of ballpoint pastes is adjusted by adding resins or polyvinylpyrrolidone. Low-volatility solvents, such as benzyl alcohol, glycols, glycol ether, or poly(ethylene glycol) are used. An example of the paste composition by weight is

30 % dye base
10 % oleic acid
5 % pigments
5 % softener
30 % phenylglycol
2 % benzyl alcohol
10 % synthetic resin
0.2 % polyvinylpyrrolidone
7.8 % 1,2-propanediol

Ballpoint pens write only when the refill is tilted downward. If the pen is held horizontally or if the tip is held upward, the force of gravity overpowers the capillarity of the system, and the pen does not function. This problem can be solved with so-called *pressurized refills*, which were described in U.S. patents many years ago [16].

Fluorinated hydrocarbons are the predominant propellants; however, air or carbon dioxide may be employed. The ballpoint paste must be extremely viscous, ca. 100 – 150 Pa s, to prevent it from flowing out of the space bet-

ween ball and bed under normal conditions. The compositions of the paste is such that it possesses thixotropic, cohesive, and adhesive properties. Apart from the dyes used in normal ballpoints, special acrylics and highly viscous polyvinylpyrrolidone give the paste the desired properties.

As a rule, ballpoint pastes should be indelible (stipulated in DIN 16554). However, erasable ballpoint refills are available. The composition of one such paste is described in [17]: rubber or polyisoprene with a molecular mass as high as 100 000 – 900 000 is dissolved in a mixture of a low-boiling and a high-boiling solvent, and ca. 20 % pigment is finely dispersed in the resulting solution. Lubricants, resins, dispersing agents, etc., can also be added to improve writing properties and adjust erasability.

3.5. Ballpoint Ink Pens

The ballpoint ink pen (Fig. 3 C) combines the advantages of the ballpoint pen and the fiber-tip pen; it ensures continuous, uniform writing. The ballpoint ink pen was first produced in Japan and has become as popular as ballpoint pens were earlier. The ballpoint ink pen has a stainless steel, cemented carbide, or ceramic ball, which rests in a plastic or stainless steel bed. The ink is free flowing. The pen writes more easily than a ballpoint pen and produces intense colors.

The inks are watery and, therefore, the pen must be equipped with a so-called tampon, a highly absorptive reservoir. The reservoir is made from bundles, about 10 cm long, of staple fibers of cellulose acetate or polyester. The tampon is filled with ink. The surface tension of the ink and capillarity enable the ink to flow out of the reservoir through a wick to the ball and onto the paper. A typical composition by weight consists of a mixture of

20 – 30 % polydiols
2 – 8 % dyes
0.5 % surfactive agents
0.5 % anticorrosive agents
0.2 % preservatives

diluted to 100 % with water.

Although the polydiols prevent the ink from drying on the ball or in the pen, they function primarily as lubricants for the ball and reduce rolling friction. The surfactive agents regulate the surface tension of the ink and adjust it to the reservoir, wick, ball bed, and ball.

3.6. Fiber-Tip Pens

The *felt-tip pen*, used predominantly for large-sized lettering and marking of packages, was the forerunner of the fiber-tip pen [18]. The felt-tip pen consists of a metal or plastic shell and a tip of cut pressed resin-soaked felt. It is filled with an ink consisting of a dye in a solvent that evaporates quickly. The felt-tip pen was developed in Japan.

Fiber-tip pens (Fig. 3 D) also originated in Japan and simplified the Oriental art of calligraphy. The fiber-tip pen is available in diverse variations and can be used for painting, marking, or fine writing.

All these pens have the same basic features: the ink supply is accommodated in a reservoir of synthetic fibers and conveyed to the writing point by a wick, which simultaneously functions as the writing point (see Fig. 5). This writing point is made from nylon, acrylonitrile, or polyester fibers or from carefully bundled, extruded fibers of a nonabrasive plastic like polyoxymethylene. The latter is especially suitable for writing and noted for uniform fine strokes.

Fiber-tip pens are assembled from the individual part by automated machines. The tip holder is surrounded with poly(vinyl chloride) or polystyrene to make the front of the pen, and this is fused to an extruded polypropylene tube. The fiber tip is placed and fixed in the front, the reservoir going into the open tube. The reservoir is filled with ink, and the tube is sealed with a plastic plug. The pressure inside the pen is kept the same as that outside by the presence of a vent, so that the ink always flows smoothly [19].

The fiber-tip pen is widely used today for both writing and drawing. As a result of its manifold applications, many types of ink have been developed. Inks having an aqueous base are used mainly for writing and drawing on paper. Inks containing volatile organic solvents and synthetic resin adhesives are used to write on or mark nonabsorbing backgrounds like glass, metal, or plastic foil. An example of the com-

position by weight of an aqueous fiber-tip ink is

20 – 30 % glycols
1 – 10 % dyes
0.2 % preservatives
0.1 % surfactive agents
2 % binding agents

diluted to 100 % with water. A typical solvent-containing ink for marking contains

2 – 15 % dyes
10 % butanol
15 % methoxypropanol
10 % binding agents

diluted to 100 % with ethanol.

Fiber-tip ink has low viscosity – if possible <4 mPa s at 25 °C – and low surface tension to guarantee good ink flow and quick drying. The aqueous inks contain 10 – 30 wt % moisturizer, such as glycols or polyglycols, to prevent the ink from drying if the pen is left open. The flowability is improved by surfactive substances. Preservatives prevent the growth of mold. Generally, acidic or basic dyes are employed, and so-called pigment preparations are used to produce nonfading inks.

Fiber-tip pens for children contain food-coloring dyes; other fiber tips contain dyes easily removed with sodium sulfite, e.g., ink blue R (Hoechst AG) or basacryl dyes (BASF). The so-called text markers contain fluorescent dyes, e.g., uranin (disodium derivative of fluorescein), pyranin (disodium derivative of 3-oxypyrene-5,8,10-trisulfonic acid), or rhodamine in combination with phthalic acid resins.

Quick-drying inks contain mainly ethanol as a solvent, in addition to butanol and other high-boiling alcohols and glycol esters. In some countries, toluene and xylene are also employed, although inclusion of aromatic solvents in goods that may be used by children is prohibited in the Federal Republic of Germany. Suitable solvents in this case are basic dyes and color bases. Natural and synthetic resins serve as film formers and improve adhesive strength.

4. Charcoal, Chalk, and Crayons

4.1. Charcoal

All types of wood form charcoal when heated in the absence of air. The best charcoal sticks for drawing are those from linden or willow.

4.2. Pastel Chalk

A mixture of nonfading organic – inorganic pigments and mineral fillers like chalk, gypsum,

powdered talc, or kaolin is added to a solution of binding agent like tragacanth gum derivatives, cellulose derivatives, alginates, gum arabic, or poly(vinyl alcohols) in a heatable – coolable mixing and kneading aggregate, and is intensively mixed. Clay or bentonite improves the plasticity of the mass and helps produce an easily pressable consistency. The amount of water added must be adjusted to the pressability of the chalk mass and can be regulated, if necessary, by evaporation of the excess. Typically, if water is ignored, the mixture consists by weight of

60 – 70 % mineral fillers
10 – 15 % organic – inorganic pigments
15 – 20 % binder solution (5 – 10 %)
3 – 5 % bentonite

The cold mass prepared in this way is pressed through the nozzle of a piston or worm press to form strands; these are marked with notches that determine the length and are then air dried. After drying, the notched strands are broken to give pieces of chalk. The amount of binding agent must be determined so that the dry sticks have sufficient tensile strength and optimal writing ability.

4.3. Blackboard Chalk

Casting Process. Anhydrous gypsum is mixed with water in a stirred mixer to give a thick lump-free paste. The paste is then passed once or twice through a 0.4-mm sieve and poured into stick-shaped forms.

After the gypsum – water mixture has set, the forms are opened and the sticks are removed. The sticks are either air dried or dried in an oven at $\leq 50\,^{\circ}C$. The mixing ratio of water to gypsum regulates the hardness and writing ability of the chalk. A water-to-gypsum ratio of 5 : 6 gives chalk that writes well and has good tensile strength. Powdered talc, kaolin, or chalk can be added to improve writing ability. Trace amounts of cellulose or gum arabic solutions bind dust. An assortment of colored chalks can be obtained by adding pigments to the basic mixture.

Pressing Process. The choice of the basic raw materials is the same as that described for pastel chalks. Only the amount of binding agent has to be adjusted to increase the hardness of the chalk.

Wetting agents are also added. These additives improve the washability of the blackboard. The pressing into strands and the preparation of individual pieces of chalk are identical with those of pastel chalks. Such a pressed chalk might have the following composition by weight:

ca. 67.5 % elutriated natural chalk
5 % powdered talc
5 % bentonite
10 % binder solution consisting of 20 wt % carboxy-
methylcellulose in water
2 % wetting agent
0.5 % preservatives
10 % water

Chalks have been produced that are efficiently pressed, can be processed safely up to the finished product, and have a high tensile strength [20].

4.4. Crayons

Crayons are produced to meet varying needs, from painting and drawing to signing. The production of crayons is carried out by either casting or pressing.

Casting. A typical composition by weight for crayon casting is

ca. 40 % C_{16}–C_{18} fatty acids
15 % microcrystalline wax
25 % ester wax
15 % mineral fillers
5 % pigments.

A typical composition for crayons that can be water painted is

ca. 15 % C_{16}–C_{18} fatty acids
30 % fatty alcohol, polyglycol ether or ester
5 % microcrystalline wax
25 % ester wax
20 % mineral filler
5 % pigment

The cast sticks are produced by melting the components and dispersing the fillers and pigments in the wax melt. A double-walled heatable container is used. The rate of rotation of the stirrer (600 – 1000 rpm) is adjusted to give a fine distribution of solid components. The homogeneous liquid crayon melt is then poured into casting forms that can be heated or cooled.

The casting temperature depends on the melting point of the wax mixture, being higher than the melting point to ensure sufficient heat capacity during the filling of the preheated casting forms. The temperatures of the wax mixture and the casting forms must be almost perfectly adjusted to produce crayons having superior surface quality and good tensile strength.

Various types of casting machines are available today, ranging from highly efficient, computerized, rotating casting machines to simple, manually operated, casting tables.

Pressing/Extruding. A typical crayon mixture for pressing has the following composition by weight:

ca. 30 % C_{16}–C_{18} fatty acids
10 % microcrystalline wax
15 % ester wax
10 % stearates
30 % kaolin
5 % pigments

The type of wax depends on the application: writing on glass, metal, or wood; painting on cloth; or other artistic purposes.

The wax mass is prepared in a kneader that can be heated or cooled. The components are homogenized, and the consistency is adjusted to guarantee a fine distribution. The cooled wax mass is pressed into strands by the heated nozzle of a piston press or extruder. The strands are cut to length and sharpened.

5. Economic Aspects

Pencils. In 1985, the number of pencil factories in the world was around 90, with a total production of ca. 4×10^9 pencils. For the last 20 years, the number of pencils produced annually in the Federal Republic of Germany has been ca. 500×10^6 ($\pm$ 15 %); more than half of these are exported. The ratio of black pencils to colored pencils has been ca. 3 : 2. The most important Western producers are the United States (ca. 1.5×10^9 pencils), Germany, Brazil, Mexico, the United Kingdom, and Japan.

Pens and Inks. Expensive, high-quality pens are made by a small number of producers, whereas inexpensive writing materials, especially fiber-tip pens, are made by a large number of producers worldwide. Reliable production information, either by quantity or by value, is not available.

6. Toxicology

In general, the substances present in ink, crayons, chalks, pencils, and other writing materials are not toxic, and all are subject to strict regulation. The end products must meet a series of legal standards that depend on the consumer group. For example, products used by children must be nontoxic in every respect. In industrialized countries, regulations cover the chemicals, the consumer goods, labeling, and other restrictions. For example, in Europe heavy-metal content must comply with EN 71, Part 3, which prohibits the use of soluble compounds of arsenic, antimony, barium, cadmium, chromium, lead, and mercury.

The poison centers in the Federal Republic of Germany and in West Berlin can provide information in cases of acute poisoning, which occur occasionally when children consume large quantities of ink or coloring matter. Any doctor in the Federal Republic of Germany has a list of these centers. Other industrialized countries have such poison centers.

Dry Cleaning

David C. Tirsell, Dow Chemical Co., Midland, Michigan 48640, United States

1. Introduction 1
2. Solvent 1
3. Process Description 4
4. Aftertreatment 5
5. References 5

1. Introduction

Dry cleaning is a process for removing soils and stains from fabrics and garments, which uses special equipment and a nonaqueous organic solvent with detergent added. Dry cleaning is popular for *cleaning natural fibers,* such as cotton and wool; it provides good cleaning without the garment shrinkage experienced with aqueous cleaning. Dry cleaning is also popular because of its *convenience,* providing garment care with equipment and skills beyond the reach of the typical consumer.

The dry-cleaning industry began in France in 1845 [1], and although it may be mature in age, it is dynamic in terms of adapting to a changing array of fabric, solvent, machinery, and regulatory issues that confront it.

Type of Operation. The industry has evolved into several forms in providing a cleaning service. The smallest operations are often the *coin-operated* dry cleaners or "coin-ops." The dry cleaning is provided as a sideline to a coin-operated laundry service, which is the principal business on the premises. The machines employed are operated by the customer or by an attendant and are usually for small-batch cleaning of 3 – 5 kg at a time; additional pressing or finishing services are not provided. Coin-ops are a significant, though declining, portion of the solvent-cleaning industry in terms of the number of establishments in North America [2], and are less prevalent in other countries.

The next largest industry segment in terms of garments cleaned per plant is *retail* or *commercial* operations. Garments are cleaned and finished by trained personnel, with aqueous cleaning a minor portion of the business. These plants may have several cleaning machines, cleaning 5 – 30 kg at a time, perhaps with more than one solvent available to give flexibility in cleaning various fabrics.

The largest volume industry segment is *industrial* cleaning. Industrial cleaning plants specialize in cleaning uniforms, protective garments, gloves, towels, or linen for large-volume institutional or industrial customers. Aqueous cleaning is often a significant portion of these businesses, with the proportion swinging between dry and aqueous cleaning with a change in relative economics or garment type chosen by the customer. Machines may have a range of 25 – 180 kg of garment capacity, again with more than one solvent usually available on-site.

2. Solvent

The characteristics of the cleaning process in whatever type of plant that is involved center on the solvent employed. Solvent *economics* is important; North American data show that the total supply cost for a retail plant, including solvent, other chemicals, hangers, and packaging materials, ranges from 9 to 11.5 % of all costs [3]. However, other factors beyond economics need to be considered, e.g., processing features, garment compatibility, and health-related issues, before an optimum solvent can be properly chosen. Because of all of these factors, four major dry-cleaning solvents are used:

1) petroleum blends, such as Stoddard solvent,
2) perchloroethylene,
3) fluorocarbon 113 (1,1,2-trichloro-1,2,2-trifluoroethane), and
4) 1,1,1-trichloroethane.

Properties of interest for a dry-cleaning solvent start with a *high affinity for greases and oils,*

the major function of the solvent in the fabric-cleaning process, balanced with a *low affinity for fabric dyes.* A good dry-cleaning solvent must also be *noncorrosive* to the common metals used in dry-cleaning equipment as well as be *chemically* and *thermally stable* under the variety of conditions experienced in the process. The solvent should be *compatible* with the wide variety of detergents and spotting chemicals in common use. The solvent needs to be sufficiently *volatile* to leave the garment essentially free of odors after drying, evaporating at a sufficiently low temperature to protect the garment fabric from damage and to allow separation from contaminants and detergents by distillation.

The last major property of interest for a dry-cleaning solvent is its relative *safety* in terms of human health and toxicity. Regulations vary throughout the world, but clearly the trend is toward a reduction in solvent use and worker exposure to all solvents. This concern for exposure, coupled with economic considerations, has encouraged the use of improved ventilation and maintenance practices, as well as recovery devices, such as refrigerated condensers or activated-carbon beds. In terms of allowable worker-exposure levels, the TLVs and MAKs of the four major solvents are given in Table 1 [4].

Solvent Selection. The balance of all of the pertinent solvent properties has resulted in a niche in the industry for each solvent. *Petroleum* has moved from a dominant position in the market in the 1930s to a stable 10 – 12 % share of the cleaning market in North America and a larger though still minority market share in Europe and Japan. Leather and suede cleaning is a major use, with the relatively gentle solvency of petroleum blends making petroleum popular for a range of textile garments as well. Although these blends are still widely used in many areas, insurance, zoning, and safety considerations often favor a nonflammable solvent substitute.

Perchloroethylene dominates the world market for dry-cleaning solvents as the most successful nonflammable replacement for petroleum, and has over 80 % of the North American dry-cleaning market. Its more aggressive solvency and lower boiling point have increased its popularity for faster and easier cleaning.

Fluorocarbon 113 was first introduced to dry cleaning in the 1960s and developed a small market on the basis of its extreme gentleness toward garments and drapes, allowing the cleaning without damage of items with more solvent-sensitive adhesives or ornamentation. The lower drying temperature reduces wrinkling and speeds finishing of a garment.

The high solvency of *1,1,1-trichloroethane,* coupled with less graying and a lower energy use, encourages a growing market for that solvent in Japan, Europe, and North America. Some of the advances in equipment, refrigeration, and recovery design developed for perchloroethylene to decrease solvent consumption and control solvent losses with the more volatile fluorocarbon solvents have contributed to machinery designed for 1,1,1-trichloroethane use.

Physical Properties. Table 2 compares the important physical properties of the four major dry-cleaning solvents. The values for petroleum solvents are expressed as ranges covering the most common blends now in use in the industry.

The importance of each property in determining the optimum solvent for a particular dry-cleaning process is as follows:

Kauri–Butanol (K–B) Value. The higher the K–B value, the greater the amount of grease and oil that will dissolve in the solvent; in addition, cleaning can be done faster with a higher K–B value solvent than with a lower K–B value solvent. Although dye stability is also affected by moisture levels and temperatures for cleaning and drying, a lower K–B value solvent is generally safer for loosely fixed dyes or fabrics that are more sensitive to solvent attack.

Surface Tension. Although modified by the addition of detergents, a lower solvent surface tension value enables the solvent to penetrate the fabric easier, and soils can be removed quicker. Once the solvent has wetted the fabric, it must have adequate solvency for oils and soils for this property to be of use.

Dielectric Constant. This property is a measure of the affinity of the solvent for polar or ionic substances, such as some soils and stains. A higher value indicates quicker removal of such stains and reduced static electricity buildup on the fabric surface. The dielectric constant also affects "graying" of fabrics, i.e., the redeposition of soils onto fabrics after they have been

Table 1. Occupational exposure limits to dry-cleaning solvents [4]

Solvent	TLV				MAK	
	TWA		STEL ∗			
	ppm	mg/m^3	ppm	mg/m^3	ppm	mg/m^3
Stoddard	100	525	(200)	(1050)		
Perchloroethylene	50	335	200	1340	50	345
1,1,2-Trichloro-1,2,2-trifluoroethane	1000	7600	1250	9500	1000	7600
1,1,1-Trichloroethane	350	1900	450	2450	200	1080

∗ The ACGIH intends to delete the values in parentheses in 1986 – 1987.

Table 2. Physical properties of dry-cleaning solvents [a] [5–10]

Property	Petroleum	Perchloro-ethylene	Fluorocarbon 113	1,1,1-Tri-chloroethane
CAS registry number	[*8052-41-3*] [b]	[*127-18-4*]	[*76-13-1*]	[*71-55-6*]
Molecular formula	hydrocarbon blends	C_2Cl_4	$C_2Cl_3F_3$	$C_2H_3Cl_3$
K–B [c] value	27 – 45	90	31	124
Surface tension (at 20 °C), N/m	0.027 – 0.050	0.0323	0.0196	0.0256
Dielectric constant	2.00 – 3.00	2.36	2.46	7.53
Relative density	0.75 – 0.85	1.620	1.577	1.315
bp, °C	150 – 210	121.0	47.6	74.0
Evaporation rate (relative to CCl_4 = 100)	6 – 9	39	170	91
Latent heat of vaporization (at *bp*), J/g	284.3	209.8	147.0	234.9
Flash point (TCC [d]), °C	38 – 60	none	none	none
Solubility of water, wt %	0.01	0.01	0.009	0.05

[c] Kauri–Butanol.
[d] Tagliabue closed cup.

initially removed in cleaning. With solvents having a higher dielectric constant, the more polar soils stay in solution rather than redepositing on the fabric surface.

Relative Density. A solvent with a higher relative density adds more mass to a garment and increases its soil-removing mechanical action, because a garment absorbs solvent in cleaning and retains it through extraction. A lower relative density solvent reduces fabric damage from this mechanical action and is desired for cleaning all but the most heavily soiled garments.

Boiling Point. The temperature needed to dry a garment is directly related to the boiling point of the solvent. A lower boiling point reduces the solubility of fabric dyes, the shrinkage of heat-sensitive fabrics, and the energy needed to distill the solvent from detergents and oils. Distillation is facilitated by large differences between the boiling point of the solvent and that of the various detergents, chemicals, and contaminants encountered.

Evaporation Rate. A higher evaporation rate shortens the time needed for garment drying, but also increases the need for greater care in machine design and solvent storage practices to avoid greater loss of solvent to the air.

Latent Heat of Vaporization. A higher value indicates a greater amount of energy needed to convert the liquid solvent to vapor in distillation or drying. Condensation of the solvent vapor is exothermic, a factor in designing adequate cooling systems.

Flash Point. For all practical purposes, three of the four solvents are nonflammable, with the flash point of petroleum dependent on the particular blend chosen. The flammability of petroleum solvents requires care in equipment design, plant lighting, and wiring.

Solubility of Water. A lower solubility of water in a solvent indicates a quicker separation of excess moisture from the solvent in the water separator. At the same time, some solubility is desired to help the detergent remove water-soluble soils.

3. Process Description

The flow of solvent within a dry-cleaning plant is shown in Figure 1.

Figure 1. Flow diagram of a typical dry-cleaning plant ∗ [10]
∗ S_l = solvent in liquid state; S_g = solvent in gaseous state.
∗∗ Clothing wet with liquid solvent.

Cleaning. The first step in the dry-cleaning process is a 3 – 15 min *soaking* and *tumbling* of the garments in the solvent in a machine much like a front-loading washing machine (see Fig. 2). A *detergent* is usually added to the solvent at base-tank concentrations of 0.50 – 1.25 vol % to aid in removing water-soluble stains (→ Laundry Detergents). An alternative procedure is to inject the detergent at a lower concentration into the wash cycle with each cleaning load, often followed by distillation of the solvent. Detergents enable the system to carry moisture above the solvent's usual water saturation point, preferably maintaining a 75 – 85 % solvent relative humidity. Most of the detergents used are anionic, although a few cationic and nonionic *surfactants* are available (→ Surfactants). All are blended by the manufacturer with inert fillers added to facilitate volume measurement. In addition, various *prespotting chemicals* may be applied to specific stains before the garment is placed into the tumbler. Solvent-soluble oils and greases are removed by the action of the solvent on the garment fibers, and insoluble soils are removed by the mechanical tumbling action.

∗ Rear view.

Drying. The *extraction* step removes most of the solvent from the garments before they are tumbled with heated air. The temperature of the air and the length of the drying cycle are determined by the solvent used and by the garment fabric material and construction. Figure 3 shows the dynamics of the drying cycle. *Water separators* on the dryer and on the still help to control solvent moisture levels by slowing the solvent flow returning to the base tank enough to allow excess water to separate.

Drying has been done traditionally in a piece of equipment separate from the washer, although the portion of the industry using nonflammable solvents is moving to the use of a single, dry-to-dry unit for both washing and drying (Fig. 2).

This unit saves space and solvent and decreases worker contact with solvent by eliminating the transfer of solvent-laden garments.

Figure 3. Reclaiming dryer system [10]

4. Aftertreatment

The solvent is continuously *filtered* during the washing cycle to remove insoluble soils, such as lint, dust, and dirt. Most processes use cartridge filters, containing a large surface area of paper for lint and soil removal and a central core of activated carbon for removing odors and dyes from the solvent. Even greater dye removal capacity is available with cartridges composed entirely of activated carbon. Cartridge filters that also contain activated clay to help remove grease and oil from the solvent are also used. Other systems are equipped with tubular filters that employ diatomaceous earth and activated carbon as the filter media, which was the standard of the industry before the more convenient cartridge filtration systems were introduced.

The solvent can be further cleansed by either continuous or batch *distillation.* Nonflammable solvents can be processed in an atmospheric still, whereas the higher boiling petroleum blends are distilled at reduced pressure. The distilled solvent is returned to the machine-base tank or other storage tank for reuse. The still bottoms are soils, greases and oils, detergent, and spotting chemicals, which are discarded appropriately.

1. Definitions

Drying oils are fatty oils (→ Fats and Fatty Oils) from different natural sources, which are able to form coating films by reaction with atmospheric oxygen. The reaction may take place with the original, unmodified oils or after modification. Oils which are able to form films on their own, without being modified, are called drying oils in the narrow sense. Oils which are able to form films if they are modified or mixed with other film-forming components are called *semidrying oils*. *Nondrying oils* are also used to produce binders for coatings formulations, but these oils and there modifications are not able to form films by reaction with atmospheric oxygen.

The reaction with atmospheric oxygen (autoxidation) takes place with unsaturated fatty acids containing more than two double bonds in the molecule. Triglycerides containing a sufficient amount of these fatty acids are drying oils in the narrow sense. Triglycerides with a significant content of fatty acids with two double bonds are semidrying oils. Oils containing predominantly fatty acids with only one double bond are not able to dry.

Drying oils in the narrow sense are linseed oil, perilla oil, tung oil, oiticica oil, and different fish oils. Semidrying oils are cottonseed oil, soybean oil, sunflower oil, safflower oil, hemp oil, poppy oil, walnut oil, sesame oil, maize oil, grape seed oils and the oils of Euphorbia, Coriander, Brassica, and Limanthes species. Peanut oil, castor oil, palm tree oil, olive oil, and almond oil are nondrying oils.

Tall oil is not a triglyceride, but a mixture of mainly unsaturated fatty acids and rosin. Tall oil is formed as a byproduct in kraft (sulfate) pulping (→ Tall Oil). Refined tall oil can be used in the same way as fatty acids from soybean oil in the coating industry.

Dehydrated castor oil is a drying oil. Dehydrated castor oil is prepared from castor oil by dehydration with sulfonic acids or at high temperatures. Dehydrated castor oil contains a rather high amount of 9,11-linoleic acid.

2. History

It was in the Stone Age that humans began to grow plants and the early advanced civilizations developed an agricultural system. Important was the cultivation of flax to produce linen, but linseed was also used for production of linseed oil. First documents which give information on the growing of flax are dated to the third dynasty in the Egyptian "Old Empire" (Pharaoh Snofru, approx. 2650 B.C.). These documents only describe the use of linseed oil as food and for lamps, there is no indication that they were used for painting. But it can be assumed that oils were used as binders for pigments in addition to inorganic binders, albumin, waxes, glues, and blood.

First paintings were artistic paintings for religious objects or for objects representing those in power. In the classic period of ancient Greece paints were also used to protect objects. Wooden ships were painted with varnishes prepared from mixtures of waxes, rosins, and oils (semidrying oils).

The first written document how to prepare oil varnishes dates back to the 11th century. The monk RODGERUS OF HELMARSHAUSEN named THEOPHILUS PRESBYTER described in his "Schedula diversarum artium" [1] how to prepare a varnish by melting amber (lat. glassa) together with linseed oil. In the Middle Ages drying oils were combined with metal oxides (white lead, red lead or minium, brown stone) not only to prepare different colors, but also to improve drying (early 13th century, HERAKLIUS, "De coloribus et artibus Romanorum" [2]). Furthermore, it was found by empirical experiments that the drying properties of oil varnishes could be improved if the oils were exposed to sunlight (stand oil), or cooked (boiled oil). Use of other driers (metal vitriols) in oil varnishes was introduced. The knowledge to prepare advanced oil varnishes was kept as an important secret [3].

In 1298 MARCO POLO reported the use of tung oil as raw material in paints for the ships in the Chinese Empire. But it was not until the late 19th century that tung oil was shipped to Europe for production of advanced oil varnishes.

In the beginning of the 15th century the use of turpentine oil (prepared by the new technique of distillation, developed in the Oriental Empires) was introduced into the preparation of oil varnishes (VAN EYCK brothers in Brugge and Gent). This invention formed the basis for the works of the most famous painters in the Netherlands at that time.

In the 16th century the first Chinese and Japanese painted articles were imported to Europe and the Europeans started to copy those techniques by using oil-based coatings. The demand for painted articles became larger and the first coating manufactories were founded in France and later in Germany. In the 18th century the method to produce sheet metal was developed in England. The coatings for the articles from sheet metal consisted of drying oil varnishes modified with furnace soot and asphalt. At the end of the 18th century the coating technique was also introduced in France and Germany. The development of traffic gave a new impetus for founding and extension of paint industries, because of an increased demand for coatings for horse coaches and ships. In the 19th century the industrial production of coatings and paints started in England, the Netherlands, and in Germany. Raw materials for the oil based coatings were linseed oil, tung oil, amber, copals, and different types of rosin. The English varnish processing plants were famous.

When the natural raw materials became rare (mainly amber and copals), chemists started to look for synthetic replacements. The first synthetic resins which were combined with oils were the phenolic resins. Later so-called oil-reactive phenolic resins were prepared. The alkyd resins formed the most important group of synthetic resins which combined the air drying of oils or oil-derived fatty acids with the physical drying of a polyester molecule. Alkyds became the most important group of resins for paints and coating from the 1930s to the 1980s and nearly totally replaced the older varnishes based on oils combined with amber, copals, and rosins. Currently alkyds are also being replaced by other binder systems.

3. Chemical Compositions [5]

Fatty Acids with Isolated Double Bonds. Important contents of drying oils are the fatty acids with isolated double bonds, i.e., linoleic, linolenic, arachidonic, and clupanodonics acid.

Linoleic acid [*60-33-3*], all-*cis*-9,12-octadecadienoic acid, M_r 280.45, *mp* $-5.0\,°C$, *bp*

(1333.2 Pa) 224 °C, iodine value 181 %, acid number 200. Various oils, which are used for the production of air-drying coatings, contain a significant amount of linoleic acid: safflower oil, sunflower oil, cottonseed oil, and soybean oil. Linoleic acid is also the main component of tall oil and a constituent of other semidrying oils which are used for specialties or artist paints.

9, 12-Linoleic acid

Linolenic acid [*463-40-1*], all-*cis*-9,12,15-octadecatrienoic acid, M_r 278.44, *mp* − 5.0 °C, *bp* (1333.2 Pa) 225 °C, iodine value 274 %, acid number 202. Linolenic acid is the main constituent of linseed oil and perilla oil.

9, 12, 15-Linolenic acid

Arachidonic acid [*7771-44-0*], all-*cis*-5,8,11,14-eicosatetraenoic acid, M_r 304.47, *mp* − 49.5 °C, iodine value 334 %, acid number 184, and *clupanodonic acid* [*2548-85-8*], all-*cis*-4,8,12,15,19-dodecosapentaenoic acid, M_r 330.52, *mp* − 78.0 °C, *bp* (666 Pa) 236 °C, iodine value 384 %, acid number 170. These fatty acids are components of fish oils, which have nearly the same properties (for coatings and varnishes) as linseed oil.

Fatty Acids with Conjugated Double Bonds. Also fatty acids with conjugated double bonds are important constituents of industrially used drying oils, i.e., α-eleostearic acid, α-licanic acid, and conjugated linoleic acid.

α-Eleostearic acid [*4337-71-7*], 9-*cis*,11-*trans*,13-*trans*-octadecatrienoic acid, M_r 278.44, *mp* + 49 °C, *bp* (1560 Pa) 235 °C, iodine value 274 %, acid number 202, is a component of tung oil.

α-Eleostearic acid

α-Licanic acid, 9-*cis*,11-*trans*,13-*trans*, *trans*-4-ketooctadecatrienoic acid, M_r 292.40, *mp* + 75 °C, iodine value 260 %, acid number 202, is a constituent of oiticica oil.

α-Licanic acid

Conjugated linoleic acid, all-*trans*-9,11-octadecadienoic acid, M_r 280.45, iodine value 260 %, acid number 202, is prepared by isomerization of 9,11-linoleic acid (see Sections 8.5) or by dehydration of ricinolic acid form castor oil (see Section 4.10).

There are other high unsaturated fatty acids in Boleco oil, Isano oil, in the oil of Marigold and in the oils of Balsaminaceae species but until now they did not find any industrial use.

4. Sources and Types [6], [7]

The composition of important drying oils is shown in Table 1. Properties of commercial drying oils are listed in Table 2.

4.1. Linseed Oil [8], [9]

Linseed oil is a drying oil. It is the oil of the seed of flax (*Linum usitatissimum*) which has been cultivated by humans since the Stone Age. Flax is mainly grown to produce fibers (linen) and is cultivated in the Baltic states, Canada, USA, Argentina, India, and since the nineties also (again) in middle Europe. The seed consists of 32 – 43 % oil, the main fatty acids are linoleic acid and linolenic acid. Linseed oil is mainly used as a raw material for paints (varnishes, stand oils, alkyds, combinations with phenolic resins, maleinized oils, urethane oils, styrolized oils) and glaziers putty and to produce linoleum, normally not for foods. Films from linseed oil are stable to water and other agents but they are not sufficiently light-stable and have a tendency for yellowing.

4.2. Perilla Oil

Perilla oil is prepared from the seeds of *Perilla fructescens* (Labiatae species), grown in India

[a] Temperature range where the oil becomes turbid during cooling.

and Indochina. The seed consists of 30 – 51 % oil. The composition of Perilla oil is similar to that of linseed oil. The oil is of local importance.

4.3. Tung Oil [10–16]

Tung oil is isolated from the nut-like seeds of the tung tree (*Aleurites fordii*, Euphorbiaceae species) in China and Japan. Tung trees are also cultivated in USA, Malawi, and Argentina. The seed consists of 25 – 45 % oil. 80 % of the oil consists of the triple unsaturated, conjugated α-eleostearic acid. Tung oil is easy to polymerize and is still being used for coatings. Tung oil is used for preparation of stand oils, for alkyds, and in combinations with phenolic resins. Tung oil is often mixed with linseed oil. Oxygen uptake during drying is lower than that of linseed oil. Films from tung oil are more elastic than those from linseed oil and more stable to yellowing. Products based on tung oil and its modifications are used for water-resistant paints (marine varnishes) and corrosion protection. A special use is the preparation of wrinkle finishes. These finishes dry very fast in the presence of driers and form regularly wrinkled surfaces (paints for machine facings).

4.4. Oiticica Oil [17]

Oiticica oil is isolated from the seeds of *Licania rigida* (Chrysobalanaceae species) in Brazil. The seed consists of 50 – 60 % oil, which consists mainly of licanic acid. Like α-eleostatic acid licanic acid contains three conjugated double bonds and has a keto group in addition. That is why oiticica oil has nearly the same properties as tung oil. It is of local interest.

4.5. Fish Oils [18–21]

The various fish oils originate from different organs of fish and differ in their composition. Oils from herring, menhaden, and sardine are of industrial interest. All of these oils contain fatty acids with 18 to 22 carbon atoms and with up to fife isolated double bonds. The drying properties of fish oils are comparable with those of linseed oil. Fish oils have a specific odor, the same holds true for products from fish oil. Fish oils are used for varnishes and alkyds for anticorrosive coatings and primers.

4.6. Safflower Oil [22], [23]

Safflower oil is a semidrying oil. It is obtained from the seeds of Safflower (*Carthamus tinctorius*, Compositae species), which is grown in Egypt, Turkey, and North America. The pure seed consists of 46 – 50 % oil. The oil contains approx. 70 % linoleic acid. Safflower oil is for high-quality foods and in the coating industry mainly for nonyellowing alkyds.

4.7. Sunflower Oil [24], [25]

Sunflower oil is also a semidrying oil. It is isolated from seeds of sunflower (*Helianthus annuus*), which is grown in Eastern Europe, China, North America, Middle America, Australia, and Eastern Africa. The seeds consist of 42 – 63 % oil. The oil contains approx. 60 % linoleic acid. In the coating industry sunflower oil is applied in high quality alkyds (nonyellowing) and in artists' paints.

4.8. Soybean Oil [26], [27]

Soybean oil is a semidrying oil. Soybeans are the fruits of soy (*Glycine max*, Leguminosae species) which is mainly grown in China, Argentina, Brazil, and USA. The beans consist to 18 – 20 % of oil. The oil contains approx. 50 % linoleic acid. Soybean oil is mainly used for foods, the paint industry uses only a small part of the large quantities of soybean oil produced. Fatty acids from soybean oil are used for alkyds. Also stand oil are prepared from soybean oil. Soybean oil is much slower drying than linseed oil. But the films are more durable and stable to yellowing.

4.9. Cottonseed Oil

Cottonseed oil is also a semidrying oil. It is obtained from the seeds of the cotton plant (*Gossypium arboreum, G. hirsutum, G. barbadeuse*, and other species), which are located on the cotton fibers. Cotton is mainly cultivated in Egypt, China, Japan, North, and Middle America. The seed kernels consists of 14 – 25 % oil. The oil contains approx. 40 % linoleic acid. Cottonseed oil is used for foods and a raw material for fatty acids for alkyds (nonyellowing).

4.10. Dehydrated Castor Oil [28–30]

Castor oil consists of a mixture of fatty acids which contain up to 90 wt % ricinoleic acid (12-hydroxy-9-octadecanoenic acid). Castor oil is isolated from the bean-like seeds of the castor plant (*Ricinus communis*), which is cultivated in Brazil, India, the Philippines, South Africa, and Southeast Europe. The seed consists of 50 – 60 wt % oil. Castor oil is a nondrying oil. In the paint industry castor oil is used for polyurethane coatings, alkyds, and for the preparation of dehydrated castor oil and its fatty acids.

Dehydrated castor oil is prepared by dehydration of castor oil with sulfonic acids and removing the crystalline hydrates. Dehydrated castor oil consists mainly of conjugated 9,11-linoleic acid and some 9,12-linoleic acid. During dehydration polymerization may occur as side reaction. Dehydrated castor oils are available with different viscosities. Dehydrated castor oil is a drying oil. The film forming properties are similar to those of tung oil, but the drying velocity of dehydrated castor oil is lower. The films are stable against yellowing, are elastic and water resistant. Dehydrated castor oil is used for oil varnishes – often combined with other oils – for pigment pastes and for printing inks.

4.11. Tall Oil (→ Tall Oil) [31–37]

Tall oil is a byproduct of the kraft (sulfate) pulping process. Crude tall oil consists of a mixture of fatty acids (45 – 55 wt %), rosin (30 – 40 wt %), and unsaponifiable components (10 – 13 wt %). The fatty acids can be separated and used as components for alkyds. Tall oil has a similar fatty acids composition as soybean oil, but normally the content of oleic acid is higher. Furthermore, tail oil fatty acids contain unusual isomers, e.g., octadecadienoic acids with double bonds in the 5-,9-, and 5-,12-positions.

5. Production

The industrial production of oils from vegetable materials (oilseeds) and animal materials (selected fish organs) by pressing (cold and hot) and extraction is described in detail in → Fats and Fatty Oils.

Refining [6], [38] (→ Fats and Fatty Oils, Chap. 6.). Some of the trace components contained in fatty oils are accepted for use of oils in foods. But when used in coatings the trace components may negatively affect the film forming properties. The impurities extracted together with fatty oils include gums, phosphatides, carbohydrates, proteins, colorants, and waxes.

The classic refining procedure consists of the following sequential, stepwise treatments of the oil: degumming, bleaching, deacidizing, and, if necessary, deodoration and dewaxing.

Degumming is performed by adding approximately 0.1 wt % of phosphoric acid or the equivalent amount of citric acid and subsequent agitation of the oil for approx. 30 min at 80 – 90 °C. The acids coagulate the gums and the coagulate is removed by filtration or by centrifugation. The process can be supported by a treatment with fuller's earth.

Bleaching removes the vegetable colors, such as chlorophyll and carotene, autoxidation products, soaps, traces of heavy metals, residues of phosphorus-containing materials, and odorants. In bleaching solid adsorbents, such as activated fuller's earth and in special cases activated carbon, are added. Bleaching is carried out in closed, agitated tanks under partial vacuum at 80 – 90 °C in the presence of 1 – 5 wt % fuller's earth for up to 30 min. Afterwards, the oil is filtered over filter presses.

Deacidizing. Crude oils may contain 1 – 3 wt % of free fatty acids. This content can be lowered to below 0.1 wt % by deacidizing. In the older process equivalent amounts of caustic soda (sodium hydroxide) are added which convert the free fatty acids to sodium soaps at 90 °C.

The process is carried out under slow stirring to avoid emulsifying. The sodium soaps are separated in form of an aqueous, concentrated soap solution (soap stock). The soap stock is separated and removed and the oil is dried under vacuum. The process is problematic regarding the residual soap contents in the oil and the oil losses by saponification.

In the newer process the fatty oils are deacidized by distillation (physical deacidizing). The oil, which is free from other impurities, which may form decomposition products during the process, is vacuum steam-distilled at 210 – 270 °C and the fatty acids are distilled off. The final acid content is 0.01 wt %. This process includes also a deodorization step. The process avoids contamination of the oil with soaps and the loss of neutral oil is lower than in the older process.

Deodorization is essentially a vacuum steam-distillation, by which odorous volatile compounds, mainly aldehydes and ketones, are driven from the nonvolatile oils. Other volatiles, such as free acids, sterols and tocopherol, are also removed. Deodorization is carried out with steam under reduced pressure at 1.0 – 2.5 kPa and 180 – 220 °C for 2 – 6 h.

Dewaxing. Linseeds and sunflower seeds are covered with a thin layer of wax. Particles of this wax were dissolved during oil pressing and extraction. Wax dissolved in the oil crystallizes during storage, especially during cooling and the oil becomes turbid. The wax contents would result in film defects in the coatings. Dewaxing consists of cooling the oil to 4 – 10 °C and holding it at this temperature until the crystallization process is finished. Then the wax is removed by filtration.

6. Testing and Specifications [39]

The properties of drying oils are tested in specific tests. The methods and target values are defined in national (DIN, DGF, ASTM, BS) and international (ISO) standards and specifications. Oils are characterized by color, acid number, saponification value, amount of unsaponifiable contents, iodine number (amount and activity of double bounds), viscosity, refractive index, and specific density (→ Fats and Fatty Oils, Chap. 11.3., see Table 2). The fatty acid composition is determined by gas and liquid chromatography [40].

7. Film Formation

7.1. Properties of Drying Oils for Film Formation

Besides their ability to dry by reaction with atmospheric oxygen, drying oils have other specific properties. Due to the long aliphatic chains of the fatty acids and their double bond content, the coatings based on oils and related products have a low viscosity and excellent wetting properties on different types of substrates (metals, wood) and pigments. That is why drying oils can form the base for "high-solids" paints, corrosion protection paints, pigment pastes, fillers, and artist's paints (→ Artists Colors). In addition, drying oils have an excellent solubility in a broad variety of solvents, including simple aliphatic hydrocarbons, which are low cost solvents, odorless, and physiologically safe. Also the oils themselves are no hazardous products. Their molecular structure imparts excellent flow and leveling properties during film formation. When cross-linking is finished the films still contain mainly aliphatic structures, which are hydrophobic and rather stable to water and some water-soluble agents. A disadvantage is their sensitivity to basic agents, which will saponify the ester groups. That is why oils and related products are not the optimum bases of waterborne coatings. But in principle the hydrophobicity of the fatty acids is an advantage also for waterborne coatings, if the drying oils are incorporated well and protected from saponification (e.g., in aqueous polyurethane dispersion based on alkyds with unsaturated fatty acids). Another disadvantage is that drying requires much time and cannot be accelerated sufficiently by higher temperatures and catalysis.

7.2. Cross-Linking by Reaction with Oxygen

The mechanisms of film formation of drying oils have been studied in investigations on oil molecules and appropriate model substances

[41]. The process occurs in different overlapping steps and the total reaction sequence and the molecular structure of the film forming polymers are complex [42], [43]. Different reaction mechanisms are followed, depending on the type of double bonds and the use of catalysts.

Oils with Nonconjugated Double Bonds. The initial autoxidation step in the case of oils with nonconjugated double bonds is the formation of hydroperoxides in allyl position to the double bonds [44–48]. Since the 11-position of linoleic and linolenic acids and – in the case of linolenic acid also the 14-position – are activated by two double bonds, the reactivity of these positions is the highest. First a radical is formed at these positions by dehydrogenation, then oxygen is added and a hydroperoxide is formed by recombination with the hydrogen radical. The reactivity of drying oils is based on the mesomeric stabilization of the radical intermediate: the unpaired electron is delocalized over several carbon atoms along the chain, and less energy is required to eliminate the hydrogen radical [49].

Additionally isomerization may take place, analytical investigation on esters of linoleic acid, for example, showed higher amounts of conjugated unsaturated 9- and 13-hydroperoxides besides hydroperoxides in 8-, 10-, 12- and 14-position [50–53].

Since the next steps of film forming lead to different higher molecular products, the analysis of these products is much more complex. Decomposition products of the film in different states, byproducts of the film-forming reaction, were investigated by mass spectroscopy [54–56]. Time-laps infrared spectroscopy was used to follow the process [57]. The analytical result led to the interpretation that the next important step is the formation of peroxy radicals by decomposition of the hydroperoxide (bimolecular disproportionation at higher concentration). Then a free-radical chain process is started by formation of oxygen bridges between fatty acid molecules and by activation of C-radicals and formation of C–C bridges. The reaction is terminated by recombination of different radicals.

The reaction is strongly influenced by temperature, light, and traces of substances which may act as catalysts or inhibitor. For example, at lower temperatures more C–O–C bonds are produced than at higher temperatures, where formation of C–C bridges is favored [58].

Oils with conjugated double bonds react differently from those with isolated double bonds. Tung oil for example absorbs less oxygen during drying, 12 wt % instead of 16 wt % in case of linseed oil [49], [59–61]. Analysis shows that the starting reaction is not the formation of hydroperoxides, but of cyclic peroxides formed by direct oxygen attack on the conjugated bond system [62]. Reaction of the peroxides with allylic methylene groups or dissociation leads to radicals. The radicals initiate a radical chain reaction, yielding C–O–C bonds and C–C bridges [63]. Due to the easy 1,4-addition of radicals to conjugated double bonds, formation of C–C bridges is preferred. The reaction is terminated by recombination of radicals or disproportionation.

7.3. Influence of Catalysts on Cross-Linking

All oxidative drying systems are formulated by adding small amounts of catalysts for drying, the so-called driers. Driers (siccatives) are oil-soluble metal salts of organic acids. The soaps with best solubility are obtained from 2-ethylhexanoic acid and naphthenic acids, in earlier times rosin acids and linoleic acid were in use [64], [65].

The soaps are produced from metal oxides or hydroxides and the acids, either by fusion or by precipitation [66]. The driers are usually dissolved in aliphatic or aromatic hydrocarbons, water-emulsifiable versions are available [67], [68].

The driers are classified in two groups, distinguished by the mode of action: active driers and auxiliary driers.

Active driers consist of metals occurring in several oxidation states and being capable to undergo redox reactions. The degree of activity may be also influenced by the molecular compatibility of the metal ion with the double bond system. Examples of metals in active driers, in order of decreasing activity, are:

Co > Fe > Mn > Ce > Pb > Zr

The metals are added to drying oils and related products (drying alkyds) at a concentration of 0.005 – 0.2 wt %. The driers speed up two reaction steps of the drying process, the activation of methylene bonds to form hydroperoxides and, more important, the redox reaction in which radicals are formed from the hydroperoxides [69–75]. If the hydroperoxides are transformed faster to radicals, the radical chain polymerization takes place more efficiently. The films are more homogeneous and become stable to dissolution in a shorter time. The metal ions are reoxidized during the process. A simplified illustration of the reaction of a drying oil with oxygen in the presence of cobalt driers is shown in Figure 1.

Suitable combinations of metals allow synergistic improvement of the total drying effect. Thus, in the past most siccatives consisted of combinations of cobalt and lead. Cobalt promotes the formation of hydroperoxides rather fast on the film surface. This is connected with the risk that the surface is cross-linked more quickly than the other coating layers. Thus, oxygen cannot diffuse into the film and wrinkles can be formed. Lead promotes hydroperoxide decomposition and accelerates polymerization and ensures that the film is formed evenly over all coating layers. Also zirconium ions form complex compounds with hydroperoxides that decompose slowly [76], zirconium has the same effect as lead. Since lead is defined as a hazardous component, most of the new drier compositions consist of mixtures of cobalt and zirconium. But also cobalt is in discussion as possible health risk. Because no real alternative to cobalt exist, the newer formulation contain smaller amounts of cobalt driers.

Auxiliary driers are soaps of metals which form only one oxidation degree but which activate the primary active driers. They do not catalyze autoxidation by themselves. Auxiliary driers are added in higher concentration than the primary driers, up to 0.6 wt % of metal. Examples of metals for auxiliary driers are calcium, barium, and zinc. The effect is explained by the basic reaction of these driers, which mainly compensate the effect of acid groups present the oil, and thus prevent precipitation of the active drier metals [77]. Auxiliary driers can also be absorbed on surfaces, e.g., from pigments instead of the active driers and the active driers are not involved in the process [78]. Barium is more toxic than lead and should no longer be used.

If the total content of metals in a film is rather high, they will be active indefinitely, causing oxidative breakdown of the film. Therefore, the amount of driers used must be carefully balanced to achieve a high degree of cross-linking but to avoid an early film decomposition.

During storage of wet paints reaction with oxygen must be avoided. The addition of oximes (methyl ethyl ketoxime) stabilizes against skin formation by reaction with oxygen in the container [79]. But now also methyl ethyl ketoxime is defined as a toxic substance and has to be substituted.

7.4. Yellowing

Films of highly unsaturated oils and related products with isolated double bonds tend to yellow under specific conditions. Films of linseed oil and related products yellow in the dark, but the yellowing will largely disappear if the film is exposed to light. Irreversible yellowing takes place if films from linseed oil and related products are aged or baked at higher temperatures. The yellowing is caused by formation of colored polyenes or quinone structures, starting from conjugated unsaturated hydroperoxides via ketones as intermediates [80–82]. The formed 1,4-diketones may also react with ammonia (farmhouses, stables, and rest rooms) to yield substituted pyrroles that can form colored products by oxidation [83], [84]. For white and other light colors linseed oil should be replaced by less yellowing products from semidrying oils, or better, alkyds based on these oils.

But also the driers (manganese, cobalt) can form complexes with oximes, which may cause discoloration in films, mainly by aging [85].

8. Modifications

The rather effective cross-linking of drying oils by reaction with atmospheric oxygen suffers from the disadvantages of a low viscosity of the unsaturated triglycerides, and the fact that the drying process has to proceed to a significant

Figure 1. Simplified reaction of a drying oil with oxygen in the presence of a cobalt drier

extent until a rather hard solvent- and chemicals-resistant coating film is formed. This process requires a lot of time. Early in history the painters tried to improve the drying properties of oils. One way was the combination of the chemical drying of oils with products which form films by physical drying (waxes, rosins, amber). When the compatibility or solubility constituted a problem, the components were heated to form stable mixtures. Furthermore, it was found that addition of particular pigments to the oils improved the drying velocity of the coating films. If oils were stored in glass bottles in the sun light or heated in the absence of oxygen the oil became more viscous. The higher viscosity of these oils results also in a reduction of drying time.

When rosins, copals, and amber became rare or were too expensive, various synthetic resins were developed as combination partners for oils. In the beginning mainly phenolic resins were used. Phenolic resins were later replaced by alkyds, which combine the chemical drying of double bonds of fatty acids with physical drying of a phthalic polyester.

8.1. Boiled Oils

Boiled oils are combinations of drying oils and stand oils with siccatives. To accomplish a homogeneous distribution of the driers in the oil, the oxides or salts of the driers are incorporated by heating the mixture to higher temperatures ($\geq 100\,°C$, boiling). The metal oxides or salts form salts with part of the fatty acids by saponification. The main bases for boiled oils is linseed oil. The driers may consist of 0.1 – 0.3 wt % cobalt or about 0.4 wt % lead, sometimes combined with 0.1 wt % of manganese.

Boiled oils are used for varnishes, mainly lithographic varnishes, and printing inks (pigment pastes).

Currently it is easier to produce varnishes in a cold process, i.e., by mixing oils and stand oils (or their mixtures with other resins) with solutions of metal driers.

8.2. Stand Oils

Stand oils are drying oils with increased viscosity. The viscosity increase results from heating of the oils in the absence of oxygen. During heating an intermolecular polymerization process occurs. The main reaction is a Diels – Alder reaction between unsaturated fatty acids, acting as partly as dienes and partly as dienophiles [86], [87]. The step that controls the reaction rate of oils with *nonconjugated double bonds* (linseed oil) is the isomerization into conjugated double bonds with concurrent trans rearrangement [88–90]. Therefore, oils with conjugated double bonds react very fast. Stand oils consist of esters of polymeric fatty acids, containing a significant amount of cyclic polymeric fatty acids [91]. The reaction may be catalyzed by the addition of small amounts of anthraquinone [92].

The process used for manufacturing of stand oils must be adjusted to the reactivity of the drying oils. Stand oils of linseed oil and soybean oil are produced in agitated stainless steel reactors at 280 – 300 °C in an inert gas stream (carbon dioxide, nitrogen). The reactor may be heated by heat-transfer oils, superheated steam, electrical induction, or resistance heating. The reactor should be equipped with water cooling facilities (half-pipes outside the reactor wall or internal cooling coils). The process is controlled by temperature and time, the progress of reaction is determined by measuring the viscosity and the acid number of samples. A linseed stand oil needs 40 – 45 h at 280 °C to attain viscosities of about 10 – 15 Pa · s. Viscosity increase of soybean oil is much slower. Decomposition products of the production of stand oils are removed by distillation, under vacuum if necessary.

Tung oil is heated in small batches (20 – 50 kg) rapidly to 260 °C, held for 7 – 12 min at that temperature (exothermic reaction takes place) and then flash-cooled with minimum the same amount of cold tung stand oil.

Stand oils are used in varnishes, oil paints, enamel varnishes, and fillers. Stand oils dry more homogeneously than their starting oils and give more elastic and water-resistant coating films. Although stand oils dry more slowly than drying alkyds, stand oils are used in combination with alkyds to raise the solids of paints to reduce the amount of solvent to evaporize. Linseed stand oil has a lower tendency for yellowing than linseed oil. Tung stand oil and soybean stand oil are even more stable to yellowing than linseed oil. Tung stand oil is superior to linseed stand oil in forming hard and water-resistant films, but the films are more brittle. Thus, linseed stand oil is often combined with tung stand oil in varnishes.

8.3. Blown Oils

For production of blown oils, drying oils are blown with air at 90 – 120 °C. During this process, hydroperoxides are formed and decompose into radicals which lead to increase in molecular mass by a radical chain transfer reaction. In addition, keto groups and hydroxy groups are formed. Blown oils have viscosities up to 3 Pa · s and are much more polar than stand oils. The drying properties are reduced.

Blown oils from linseed oil and soybean oil are used as plasticizers for polymers which dry physically, for printing inks, for putties, and sealings. Blown linseed oil is used for core binders for casting.

8.4. Factice, Sulfurized Oils

Factice is a mixture of drying oils with sulfur or disulfur dichloride. Like oxygen, sulfur is able to react with the double bond system in a radical chain reaction. The polymerization occurs very effectively over the whole film layer. Varnishes containing factice oils can be applied in a wet-on-wet process.

8.5. Isomerized Oils

During isomerization isolated double bonds are transferred into conjugated double bonds and cis double bonds are converted into trans double bonds. The process is carried out with metal catalysts at 100 – 140 °C. Linseed oil and safflower oil are isomerized in the presence of a nickel catalyst, finely distributed on diatomaceous earth or active carbon [93–95]. Isomerized oils take up less oxygen during drying than the corresponding starting oils and form elastic films with higher water resistance.

The alkali isomerization process is carried out with the methyl ester of fatty acids to afford fatty acids with conjugated double bonds. They are used in alkyds, mainly for stoving enamels [96–98].

8.6. Copolymers

Copolymers of drying oils are produced by heating unsaturated oils with unsaturated monomers [99], [100], preferably styrene. Additionally, vinyltoluene [101], α-methylstyrene, dicyclopentadiene [102], pentadiene, and indene [103] are used as monomers, also methylmethacrylate is described. Copolymerization is carried out at higher temperatures, catalysts are peroxides, e.g., di-*tert* butyl peroxide [104]. The process may be run in bulk or in solution. A feed process for monomer dosing is preferred for most exothermic reactions to guarantee a reproducible process. Unreacted monomers are distilled off after the process. The content of styrene in styrenated oils is 20 to 45 wt %. During the polymerization of nonconjugated oils and styrene, grafting of styrene molecules to chains onto oil molecules occurs. Starting from the active methylene groups of the oil, polysterene bridges are formed [105], [106]. It is important to avoid the formation of styrene homopolymer, because it is not compatible with the oil. *Conjugated oils* form Diels – Alder adducts connected by short bridges of polystyrene, the viscosity increases more rapidly than the viscosity resulting from the grafting nonconjugated oils [107], [108]. The compatibility of styrenated oils with other polymers is limited. Using vinyltoluene, α-methylstyrene, or dicyclopentadiene gives copolymers with a much better compatibility and solubility. Cyclopentadiene and indene form only Diels – Alder adducts both with conjugated and nonconjugated oils.

Copolymers of oils have improved drying properties, the resulting films are harder and more resistant to water and chemical agents than the films from drying oils and alkyds.

8.7. Maleinized Oils [109–112]

Maleic anhydride is a dienophile and easily reacts with conjugated double bonds in a Diels – Alder reaction to form a substituted cyclohexane dicarboxylic anhydride. The process is carried out at 80 – 120 °C [113], [114]. Nonconjugated unsaturated oils react with maleic anhydride in a ene reaction via the active methylene groups to form substituted succinic anhydride derivatives [115], [116]. But also Diels – Alder reactions may take place if the isolated double bonds are converted into conjugated during the process. The reaction is carried out at 180 – 240 °C.

Maleinized oils with 5 – 8 wt % of maleic anhydride (less than 1 mol per triglyceride) are esterified with glycerol and other polyols to form oil-modified polyesters. Their properties are similar to those of alkyds, and oil-modified polyesters dry faster than the original oils and form harder and more water-resistant films.

Maleinized oils with 16 – 24 wt % maleic anhydride are reacted with water or alcohols to yield maleinized oils with high acid numbers (100 – 200). After neutralization of the acid groups with ammonia or – more preferably – amines, the maleinized oil becomes water-thinnable [117]. The product is combined with phenolic or amino resins [118–120]. These water-thinnable combinations are mainly used as anticorrosive primers for electrodeposition. In electrodeposition the part to be coated is immersed in a tank and direct current is applied. In the process the binder systems (together with pigments and additives) are coagulated on the anode, which is the surface of the substrate to be coated [121–123]. The coagulated film can be rinsed with water and is then stoved at 175 – 180 °C for 20 – 30 min. The process ensures that film formation takes place on all parts which are immersed in the tank. Starting in the 1960s, such systems gained importance as corrosion protective primers in the automotive industry.

In the late 1970s the systems were mainly substituted by a resin system for a cathodic deposition process. But the maleinic oils are still in use for industrial primers.

8.8. Oil Boiling with Rosin, Copal, and Amber

In the past oils – and also drying oils – were used as solvent for different natural resins. The

target was to convert the natural resins into a suitable form for application and to combine the film properties of the natural resins with the drying properties of the oil. The higher the melting point of the natural resins, the better the film properties. Copals were better than rosins, and amber was better than copals. To improve the properties of rosins, rosins were transferred into rosin salts with calcium and zinc, into rosin esters with glycerol and pentaerythrol, and maleinized and esterified (→ Resins, Natural, Chap. 5.5.). It was not easy to melt the high molecular natural resins (copals and amber) and starting in England special know-how was gathered for this process.

The combinations of oils, different natural resins and related products and siccatives formed the basis for the oil varnishes, the first industrially used coatings.

8.9. Oil Boiling with Phenolic Resins

When the natural resins became rare the investigation to prepare synthetic resins began. The first synthetic resins used for industrial coatings were the phenolic resins (→ Phenolic Resins). But the normal phenolic resins (resols) are not compatible with oil. The first step to overcome the problem was the combination of rosin-modified phenolic resins with drying oils [124]. The second step was the preparation of so-called alkylphenolic resins (from alkyl-substituted phenols) [125], [126]. These alkylphenolic resins are able to react with oils, preferable tung oil, to yield adducts between the double bond system and the methylol and OH group of the phenolic resin [127]. The process is carried out at 240 °C, using a mixture of 2–4 parts tung oil and 1 part alkylphenolic resin. The reaction products have good drying properties and the films are highly resistant to water and chemicals. The product were used for industrial coatings and especially for yacht varnishes. For this application they were much more suited than alkyd varnishes. These combinations are often replaced by polyurethane coatings, but yacht varnishes are still available.

8.10. Modifications by Transesterification

If drying oils are heated with an excess of polyols, glycerol, pentaerythrol, or dipentaerythrol at 230 to 260 °C, mono- and diglycerides [128–131] are obtained. The alcoholysis (transesterification) is an equilibrium process. Salts of alkali or alkaline-earth metals serve as catalysts. To avoid the formation of incompatibilities of the catalyst in the reaction mixture or the final product, the use of lithium salts is preferred. The reaction is controlled by the added quantity of polyols, the reactivity of the OH groups, the temperature, and the time. The progress of the reaction is determined by measuring the solubility of the reaction mixture in methanol or ethanol. Transesterification products are starting materials for production of alkyds, urethane oils, and urethane alkyds.

Alkyds (→ Alkyd Resins) are prepared by reaction of the transesterification products and phthalic anhydride. The process was developed in 1927 and was the first important process for production of air-drying alkyds.

Urethane oils [132], [133] are prepared from the transesterification products and toluylene diisocyanate. Products obtained by reaction of the transesterification products with mixtures of phthalic anhydride (first esterified) and toluylene diisocyanate are called urethane alkyds. Urethane oils and urethane alkyds dry faster than alkyds to give harder and more resistant films, but the films are not weather-resistant. Urethane oils and urethane alkyds are used for wood coatings, preferably for parquet varnishes.

8.11. Modifications Based on Fatty Acids

Fatty acids are produced from drying oils by saponification. The fatty acids are the basis for the production of alkyds (→ Alkyd Resins) and epoxy esters. In contrast to oil varnishes and paints, alkyds and epoxy esters based on unsaturated fatty acids are still important coating materials.

9. Application, Importance, and Future Aspects

Oil varnishes and oil paints have been largely replaced by more modern systems, mainly alkyds, but there are still some oil paint products on the market. For people, who want to use natural raw materials, oil-based paints are still of interest for furniture coatings (mainly for "do-it-yourself"-applications), but there is nearly no industrial use. Products derived from drying oils, i.e., air-dryings alkyds and epoxy esters, and maleinized oils, still play a more important role in the paint industry. In Germany the market volume of solventborne coating materials is estimated to be approximately 300 000 t in 1999. Oil paints and oil varnishes have a share of only 0.6 %, but this is approximately 12 % more than in 1998. Coatings based on air-drying alkyds made up nearly 20 % of this volume, but the amount is decreasing in comparison to 1998 [134].

Advantages of oil-based or fatty acid-based coating materials are: excellent wetting of pigments and surfaces, easy application, good flow and leveling, low health risks, environmental compatibility, and optimum hydrophobicity of films. However, they suffer from two important disadvantages: (1) Oil- or fatty acid-based coating materials need too much time for film formation by air drying to be used in advanced industrial coatings application processes (e.g., automotive coating application) and (2) these coating materials are not easy to transfer into water-based systems – to avoid organic solvents for ecological and economical reasons – due to the sensitivity to react by saponification. On the other hand, since the 1980s there has been growing interest to increase the use of natural renewable raw materials. Drying oils and related products meet this demand. Several institutes started to investigate the possibility to decrease the agricultural food production in Europe and to replace growing of plants for food partly by growing of plants which produce raw materials for industrial use [135–140]. There are new proposals to grow plants which contain drying or semidrying oils or plants which contain fatty acids plus other chemically reactive groups.

1. Survey

1.1. History [10]

In 1834 Runge isolated aniline from coal tar and observed the formation of aniline black on oxidation. Picric acid was used as a silk dye in 1849. The first synthetic dye of technical significance, called Mauveine after its mauve color, was obtained in 1856 by Perkin in an attempt to synthesize quinine. With his father and brother, he founded the first factory to manufacture synthetic dyes in Greenford Green, near London. This was the start of the dye and pigment industry. The year 1856 also saw the synthesis of fuchsine. The manufacture of fuchsine, later called magenta, began in 1859.

In 1862 GRIESS created *azo dye* chemistry with the discovery of diazo compounds [11]. Among the earliest *azine dyes* were induline in 1863 and nigrosine in 1867. The first synthesis of an *anthraquinone dye* was that of alizarin in 1868. The first *sulfur dye* was obtained in 1873, and indigo was synthesized in 1878.

Progress became very rapid with the advent of structural organic chemistry; many thousands of dyes were synthesized within a few decades. Many of the large chemical plants in operation in Germany and Switzerland today were built as dye factories in the second half of the 19th century. The manufacture of dyes has spread from Europe throughout the world; Western Europe still accounts for ca. 40 % of the worldwide total.

Azo Dyes. Bismarck Brown was introduced in 1863, and chrysoidin was introduced in 1875. Azoic dyeing became possible in 1880 with the formation of insoluble azo dyes on the fiber. In 1884 the use of benzidine-based disazo dyes such as Congo Red made possible the dyeing of cotton without a mordant.

Post-treatment of dihydroxy azo dyes with chromium salts was introduced in 1893, and the use of arylamides of 2-hydroxy-3-naphthoic acid (Naphtol AS) as coupling components was first seen in 1911.

Simple 1 : 1 preformed chromium and copper complexes were first described in 1912 leading to 2 : 1 chromium and cobalt complexes specifically designed for wool in 1949. Disperse dyes for acetate fiber became available in 1921, and triazine polyazo dyes were introduced in 1922. Reactive dyes for wool and cellulose were introduced in 1952 and 1956, respectively.

Anthraquinone Dyes. The early history is reviewed in [12]. Alizarin (1,2-dihydroxyanthraquinone) was first synthesized in 1868. Mercury-catalyzed sulfonation of anthraquinone was discovered in 1901. Indanthrene Blue, the first anthraquinone vat dye, was produced in 1901. Benzanthrone, as well as vat dyes prepared from it, followed in 1904. The phthaloyl acridones, vat dyes of high lightfastness were discovered ca. 1910, and Caledon Jade Green (dimethoxy violanthrone) was an important discovery in 1920. Sulfuric esters of leuco vat dyes were introduced in 1924.

Sulfur Dyes. Cachou de Laval, the first useful sulfur dye, was discovered in 1873. Improvements followed in 1893, and in 1897, Immedial Black V Extra became the first major commercial product.

Indigo and Indigoid Dyes. After the historic synthesis of indigo by VON BAEYER in 1878, more economical methods were devised, and production began in 1897.

Sodium amide was first used in conversion of phenylglycine to indigo in 1901; this process is still employed. Thioindigo was first synthesized in 1906, and stable water-soluble sulfuric esters of leuco indigoid dyes were introduced in 1921.

Triphenylmethane and Xanthene Dyes. Phthaleins such as phenolphthalein and fluorescein were discovered by VON BAEYER in 1871. Malachite Green and Fuchsine S were introduced in 1877, followed in 1883 by Crystal Violet. The important xanthene dye Rhodamine B was discovered in 1877.

Phthalocyanines [13]: Copper phthalocyanine was discovered in 1927 [14], and its structure elucidated in 1933. In 1935 it came on the market as Monastral Fast Blue B (ICI) and as Heliogen Blue B (I. G.). In 1951 the discovery was made that metal phthalocyanines can be produced on the fiber [15].

1.2. Classification and Definitions

Dyes and pigments can be classified according to chemical structure or the mode of application. The most important commercial products are the azo, anthraquinone, sulfur, indigoid, triphenylmethane, and phthalocyanine dyes. The principal chromophores are as follows (Dye classes marked with an asterisk and those referred to by an arrow are separate keywords in this Encyclopedia):

Acridine (→ Triarylmethane and Diarylmethane Dyes)
Anthraquinone *
Azine (including oxazine and thiazine) *
Azo *
Benzoquinone and naphthoquinone *

Formazan (→ Metal Complex Dyes)
Indigoid ∗
Metal complex ∗
Methine (including azomethine) ∗
Naphthalamide ∗
Nitro ∗
Nitroso ∗
Phthalocyanine ∗
Quinacridone (→ Pigments, Organic)
Quinophthalone (→ Methine Dyes and Pigments)
Stilbene (→ Optical Brighteners ; → Azo Dyes)
Sulfur ∗
Tri- and diarylmethane ∗
Xanthene (→ Triarylmethane Dyes and Diarylmethane Dyes)

Application. The same chromophores are found in both dyes and pigments. The former are applied mainly to textiles, but also to paper, leather, food and other products. Pigments are used in paints, inks, and polymers. Other specialized applications are covered in separate articles (→ Artist's Colors ; → Ceramic Colorants ; → Laser Dyes ; → Photography).

The Colour Index [16] is based on the classification summarized in Table 1. Principal areas of application are emphasized. It can be seen, for example, that for dyeing cotton one can choose among five classes of dyes. Every dye and pigment manufacturing company has its own trademark to identify each product class. The Colour Index (C.I.) lists all these (some 8000 products) and, when chemical constitutions are available, the equivalent products under the same number [16]. The C. I. names and numbers are indexed in this Encyclopedia.

It is worth noting that by 1980 the world production of the main synthetic fibers (polyester, polyamide, acrylic, viscose, and acetate) had reached equality with the world production of natural fibers (cotton and wool). It follows that the consumption of textile dyes is about equally divided between natural and synthetic fibers.

1.3. Manufacture

This survey considers unit operations of general significance, but excludes unit processes such as nitration, reduction, and sulfonation, important enough to be treated separately (→ Nitro Compounds, Aromatic; → Reduction ; → Benzenesulfonic Acids Their and Derivatives). The manufacture of the chemical, the so-called color paste, and that of the finished product are separate operations, although the two are often fully integrated. Finishing (or conditioning) changes the physical form, most simply by drying and grinding; this technology is as important as the chemical synthesis, especially in the manufacture of pigments and water-insoluble dyes. These two classes should be distinguished from water-soluble dyes at the finishing stage. Earlier processing stages may also have a significant influence on the final physical form.

Although unit operations are fully described in the B-series, the dye and pigment industry is rarely mentioned, because it has very few requirements peculiar to itself.

1.3.1. Unit Operations

Reactants and the reaction medium (water or solvent) are delivered to the reactor using standard materials handling procedures. The dye industry usually employs a batch process; agitation and mixing are critical.

Crystallization and Filtration. Crystallization of the final product requires careful control to obtain the most desirable physical form; the filtration equipment is chosen accordingly, with a view to both speed and maximum liquid removal. The suspension to be filtered usually contains 1 – 10 % solids with a concentration to an average of 50 % after filtration.

Crystallization is effected by one or more of the following techniques:

1) Variation of reaction conditions
2) Cooling a solution below the crystallization temperature
3) Solvent evaporation
4) Dilution, usually by addition to water
5) Adjustment of pH
6) Salting-out by addition of an inorganic cation, usually Na in the form of salt

Table 1. Dye classification

Class	Properties	Chromophores (main)	Substrate suitability					
			Wool	Cotton, Viscose	Polyester	Polyamide	Acrylic	Others
Acid	water-soluble, anionic	azo (incl. premetallized chromium complexes), anthraquinone	X			X		leather silk
Azoic	water-insoluble azo dye formed on fiber	azo		X				
Basic	water-soluble, cationic	triphenylmethane, methine, modified azo, anthraquinone					X	acid-modified synthetics paper
Direct	water-soluble, anionic	azo (incl. copper complexes), stilbene, phthalocyanine		X				paper
Disperse	water-insoluble, nonionic	azo, anthraquinone, nitro			X	X		acetate
Mordant	water-soluble, anionic, chromium complex formed on fiber	azo	X					
Reactive	water-soluble, anionic, forms covalent bond with substrate	azo (incl. premetallized), anthraquinone, phthalocyanine	X	X				
Sulfur	temporarily solubilized with alkali sulfide	sulfur		X				
Vat	temporarily solubilized as leuco ester with alkaline sodium hydrosulfite	anthraquinone indigoid		X				
Pigment	water-insoluble, nonionic	azo anthraquinone phthalocyanine quinacridone						polymers, paints, inks, etc.

The choice of filter is based on the physical form of the product and the availability of equipment. The physical form may need to be adapted to an existing filter, or the best combination of physical form with efficient filtration may need to be developed. A complication may be introduced by the need to wash the product.

Filters are available in six types: nutsch filters (vacuum filters), pressure filters, filter presses, diaphragm presses, continuous vacuum filters, and centrifuges. The filtration product is usually termed the color paste.

Drying. Drying is usually necessary unless the color paste is to be converted to a liquid product. The water content of these pastes varies from 20 to 80 %; drying costs vary accordingly.

The choice of dryer is governed by the following:

1) *Scale,* i.e., quantity of product and of water to be removed
2) *Physical form* and characteristics of feedstock
3) *Hazards* or other decomposition problems caused by drying temperatures of 50 – 180 °C
4) *Properties* of the product
5) *Physical form requirements* for subsequent processing or marketing
6) *Capital and operating costs*

The following dryer types are used: ovens, agitated vacuum dryers, filter dryers, spray dryers, drum dryers, through-circulation dryers, and fluidized-bed dryers. Ovens produce dry lumps, spray dryers produce grains. Other types of dryers produce a variety of aggregated forms.

Milling and Grinding. Particle size is reduced by grinding or milling. Dry grinding is usually carried out in impact mills equipped to control dust. Continuous drying methods have been developed to eliminate the final product comminution stage.

The ball mill, consisting of a rotating or vibrating cylinder containing hard balls, has always been limited in use for dry grinding because of product removal problems. It has been superseded by sand and bead mills. Wet milling is increasingly important for pigments and disperse dyes. Many designs consist of vertical or horizontal cylinders equipped with high-speed agitators and continuous feed and discharge. Sand or fine glass beads remain in the cylinder and effect comminution as the suspension of dye or pigment flows through. The objective is to achieve uniform particle-size distribution with a minimum expenditure of energy. A multishear mixer in the feed vessel sometimes provides a premilling stage.

1.3.2. Formulation and Standardization

The tendency has been to integrate standardization with color manufacture. Drying is frequently integrated with color production; modern continuous dryers afford a wet-standardized product ready for sale. This is made possible by the use of rapid instrumental color matching against standard products. The finishing stage includes the incorporation of diluents and dispersing, wetting, and dust-control agents. The diluents may be common salt or Glauber's salt, but if electrolytes are undesirable, urea or dextrine may be used. Dyes isolated as free acids may be blended with alkali (sodium carbonate, sodium hydrogen carbonate, or trisodium phosphate) to form the sodium salt when the mixture is dissolved. Reactive dyes are buffered to prevent hydrolysis during storage.

Table 2. Physical form specifications

Form	Specification	
	as sold	as used
Solids		
Grains	dust-free	no precipitation
Powders	good solubility or dispersibility	no adverse additives effects
	good wetting	foam-free
Liquids		
Ionic	stable to storage	stable throughout dyeing
	pourable	
Nonionic	speck-free	

To meet market needs, it is often necessary to produce a given dye in more than one strength or brand. For hygienic reasons, an increasing number of water-soluble dyes are being produced in

aggregated or granular rather than powder form by the use of modified drying techniques.

These procedures apply equally to liquid products, such as solutions of basic dyes or dispersions of water-soluble dyes. Water, or occasionally an organic solvent, is the diluent, but additives are usually required to control pH, viscosity, stability, freezing, and evaporation.

Table 2 shows physical specifications for textile dyes.

1.4. Applications

In dyeing processes, textiles, paper, or leather are usually heated in a solution or suspension of dye. In printing, a dye or pigment paste is applied to the surface of the substrate and then heated. Increasingly sophisticated equipment is employed toward energy saving and cost reduction [17].

1.4.1. Wool

Wool consists of a protein called keratin, which is built from 18 different amino acids of the general formula $H_2N-CHR-COOH$. The chains have the general form

and are united at intervals by bridges derived from cystine.

Some of the side chains end in amino groups and others in carboxyl groups; internal salt formation binds the molecules together by electrovalent linkages. The average molecular mass of keratin is ca. 60 000.

Wool has the most complex physical structure of all textile fibers. A central cortex composed of a bundle of fibrils is surrounded by a scaly covering known as the cuticle. Coarse wools may also contain a medulla, or central canal. Affinity for dyes is not uniform throughout the fiber, the cuticle being hydrophobic and resistant to penetration; however, it does not usually extend to the fiber tips. It is subject to damage during processing, where alkaline conditions are especially destructive, causing rupture of the cystine links. The fiber is more resistant to acid, but prolonged boiling causes hydrolysis of peptide linkages. Therefore, uniform dyeing of wool is difficult, especially with a mixture of dyes. By virtue of its carboxylic and amino groups, wool has affinity for basic and acid dyes but the former are rarely used. Almost all acid dyes contain the sulfonic acid group which causes adsorption by ionic attraction to the basic groups in wool. The resulting link is easily broken, however, and cannot fully explain the washfastness shown by many acid dyes. In these cases attachment to the fiber appears to depend mainly on nonpolar van der Waals forces, the strength of which is proportional to the area of contact. Acid dyes are of two general types, the leveling type that diffuses readily through the fiber and the milling type that does not and is, thus, faster to wet treatment. Leveling dyes are applied in the presence of sulfuric acid (pH 2.5 – 3.0) and Glauber's salt, but milling dyes, having greater affinity, must be applied under mildly acidic conditions (acetic acid, pH 4.5 – 5.5); in some cases, ammonium sulfate is used (pH 6.0 – 8.5). In more strongly acidic conditions, neutral-dyeing acid dyes give uneven shades.

The washfastness of wool dyed with an anthraquinone dye containing an *o*-dihydroxy group can be improved by posttreatment with a chromium salt such as sodium or potassium dichromate. Early in the 20th century, it was found that *o,o′*-dihydroxyazo dyes give similar results. Such dyeings are known as Chrome colors; their exceptional fastness is due to the formation of chromium complexes within the fiber.

Afterchroming modifies shades and creates difficulties in color matching. This disadvantage has been overcome by the use of preformed metal complexes (→ Metal Complex Dyes). The early 1 : 1 chromium complexes were applied by prolonged boiling in a strongly acidic bath which damaged the fiber. The later 1 : 2 chromium complexes required less severe conditions. Unsymmetrical 1 : 2 metal complexes meet still more varied requirements.

Reactive wool dyes provide bright fast shades when applied at carefully controlled pH. Leveling is controlled by temperature and additives.

Wool may be dyed in several forms:

1) *Loose wool* fleece has been merely scoured free of natural grease and minerals. *Slubbing* consists of thick, loose untwisted ropes of parallel wool fibers. Such wools are usually dyed with the faster acid and chrome dyes. The fibers are more easily penetrated at this stage than in yarn or piece form.
2) Yarn, i.e., in thread form, is standard for carpets or knitting yarn. Acid dyes are most commonly employed, with chrome dyes and 1 : 2 metal complexes used less often.
3) *Piece goods,* i.e., woven or knitted fabric, provide the cheapest method and is used whenever possible. It is, of course, limited to solid shades, as in dress fabrics. Dyes with good leveling and fastness properties are required.

Various finishing treatments may be employed after dyeing. *Crabbing* gives worsteds a more or less permanent set, and *potting* confers a characteristicly smooth surface on such materials for dress suits; both involve treatment with hot water. A more drastic process known as *milling* involves prolonged treatment between rollers with soap and sodium carbonate solutions; this causes the wool to "felt," i.e., become more compact. Dyes must be fast to these processes without loss of color or staining of white or lightly colored threads in the fabric.

1.4.2. Cellulosics

Cotton is almost pure cellulose [*9004-34-6*], a linear polymer of β-D-glucose units (→ Cellulose). The empirical formula is $(C_6H_{10}O_5)_n$ with *n* between 600 and 1000 and molecular mass upward of 100 000.

Viscose rayon is regenerated wood cellulose. Although similar chemically, cotton and viscose differ somewhat in structure and, therefore, in dyeing properties. Both the chemistry (especially the presence of the hydroxyl groups) and the physics of the fiber are important in dyeing.

Direct dyes are substantive to cellulose without a mordant; historically they replaced naturally occurring mordant dyes. Direct dyes are the most important single class, and are simple to use. Optimum conditions vary, but dyeing is usually carried out at or near the boiling point in the presence of common salt or Glauber's salt; the ratio of liquor to goods is fairly high (typically 20 : 1 in fabric-dyeing machinery). The lightfastness of metallizable dyes can be increased by posttreatment with copper salts, and washfastness can often be improved by resin treatment. Shades are greatly affected by metal salts but less so by resins imparting crease resistance.

Reactive dyes offer brighter shades of higher wetfastness than direct dyes. Batchwise application resembles dyeing with direct dyes ("salting" onto the fiber from hot aqueous solution) but is followed by alkaline treatment to fix the dye on the fiber by a chemical reaction with the hydroxyl groups of the cellulose (→ Reactive Dyes).

Continuous dyeing and printing are attractive for reactive dyes, permitting the alkali to be applied simultaneously in a single-stage process. All of the important chromophores are available as combinations with a variety of reactive groups [18].

Vat dyes are more expensive than direct or reactive dyes, but are used when the highest lightfastness is required, for example, for home-furnishing fabrics. They are applied from an aqueous solution of the leuco dye (vatting stage) obtained by alkaline reduction with sodium hydrosulfite (dithionite). Oxidation reforms the insoluble dye within the substrate. Subsequent treatment in a boiling detergent solution gives maximal fastness.

Sulfur dyes are applied similarly to vat dyes, with the dye being dissolved by sodium sulfide reduction; sodium carbonate may also be present. Dichromate is commonly used as an oxidant. Dull brown to black shades are obtained cheaply by this process but fastness properties are modest. The use of sulfide may create environmental problems, however.

Azoic colors are insoluble azo dyes produced from the intermediates directly on the fiber. They were once important but are now in marked decline. Their excellent properties are offset by their limited shade range and the complexity of the application procedure compared with, for example, those of reactive dyes. In the simplest form of the process, a coupling component with affinity for the fiber is applied from an alkaline solution to cotton or other cellulosic material. After removal of excess liquor, the color is developed on the fiber by immersion in a bath containing a diazonium compound. Pigment particles formed within the fiber are aggregated by hot soaping, which enhances resistance to wet treatment.

1.4.3. Polyester

Poly(ethylene terephthalate) [*25038-59-9*], M_r 15 000 – 20 000, is highly hydrophobic and

lacks reactive groups (→ Fibers, 4. Synthetic Organic). The tightly packed molecules do not easily accommodate dye molecules. Disperse dyes applied at the boiling point under conditions suitable for acetate or polyamide give only pale shades; temperatures of 120 – 130 °C in pressure equipment are usually required (→ Disperse Dyes).

A simpler process employed at atmospheric pressure makes use of an agent called a *carrier.* This is an emulsion of an aromatic compound such as methylnaphthalene, diphenyl, or trichlorobenzene. Carriers are really plasticizers that increase the segmental mobility of the polyester chain and, thus, facilitate entry of dye molecules. This method creates environmental problems, and removal of the carrier after dyeing is troublesome, but it is still widely used for polyester-wool fabric.

The *Thermosol process* is used for dyeing polyester in cellulosic blends. The scoured fabric is padded with a disperse dye and a migration inhibitor. The fabric is then dried and heated to 175 – 200 °C for ca. 1 min, during which the applied dye is absorbed by the polyester component. The cellulosic component can be dyed simultaneously or afterwards.

Slow diffusion of dyes below 100 °C usually creates good wetfastness properties. Lightfastness can be improved by structural modification of the dye molecule. Some small nonionic molecules are subject to sublimation when treated with a hot iron. This property can be exploited in transfer printing, a process of minor importance.

1.4.4. Polyamide

The commercial products include Nylon 6,6 [*9011-55-6*] (adipic acid copolymer with hexamethylene diamine, average M_r 12 000 – 20 000), and Nylon 6 [*25038-54-4*] (polymerized caprolactam).

Nylon 6,6

Nylon 6

Nylon 6,6 and Nylon 6 can be dyed by certain disperse dyes that show good leveling properties and are more effective than acid dyes in concealing irregularities in the filament. For wetfastness, however, acid milling or premetallized dyes are required; these dyes withstand wet treatments even better on polyamide, with its hydrophobic character, than on wool. Lightfastness is usually slightly lower on polyamide than on wool. The leveling properties of acid milling and premetallized dyes are poor on polyamide, especially Nylon 6, which contains a higher proportion of free amino groups and has greater affinity for acid dyes.

1.4.5. Acrylics

Unmodified polyacrylonitrile [*25014-41-9*] is so difficult to dye that copolymers are used to introduce acidic or basic sites. Thus, 4-styrenesulfonic acid [*98-70-4*] copolymer gives a fiber that accepts basic dyes.

The classical basic dyes, e.g., triphenylmethanes, give strong shades that are usually poor in lightfastness and modified basic dyes have been developed especially for polyacrylonitrile. These are applied from aqueous solution with careful temperature control up to the boiling point to achieve level dyeing. Fastness properties are excellent.

Unmodified polyacrylonitrile

Acid-modified polyacrylonitrile

1.4.6. Pigments

A pigment is an insoluble coloring matter employed in a medium such as a paint or polymer [19]. Physical properties such as crystal form, tinctorial strength, transparency, and rheology are much more important than with water-soluble dyes (inorganic and organic pigments are treated in separate articles; → Pigments, Inorganic and → Pigments, Organic).

Toners are precipitated complexes of water-soluble dyes, e.g., calcium or barium salts of sulfonated azo dyes or phosphomolybdate salts of basic dyes. Lakes are similar to toners, but are precipitated in the presence of a substrate such as alumina to give a more dilute product. Extended (or reduced) pigments are toners or lakes diluted further with alumina or calcium carbonate.

As with textile dyes, the azo chromophore predominates, supplemented by phthalocyanine blues and greens and quinacridone reds where the highest fastness is required. Vat dyes are also used in pigment form.

1.5. Economic Aspects

Worldwide production of dyes and pigments is estimated to be ca. 750 000 t/a [20]. Very few products have a worldwide demand of more than 1000 t; 100 – 200 t/a is a more typical figure. These requirements are met by a large number of competing suppliers.

The worldwide growth since the mid 1930, shown in Table 3, reflects the decline of the Western European share from 95 % at the beginning of the century to ca. 40 %. About half the Western European production is based in the Federal Republic of Germany; Switzerland and the United Kingdom are the other principal exporters. The major Western European manufacturers have subsidiaries in the United States and elsewhere.

Figures after 1974 are available for United States [21] and Japan [22] but not for the OECD. However, United Nations statistics show a slump in 1975 followed by a leveling of world production from 1974 (Table 3) through to the 1980s [23]. The real value of production (ca. $ 5×10^9 by 1980) shows slight expansion.

Tonnage figures can be misleading since they do not take account of product strength. There is little doubt that the trend over the last ten years has been for increasing strengths and that this accounts for the apparent lack of tonnage growth.

On a worldwide basis, the consumption of dyes and pigments is ca. 200 g per person per annum; the figures for developed countries are much higher, e.g., 650 g/a for the Federal Republic of Germany. This covers everything from clothing to cars: ca. 60 % is allotted to textiles, 25 % to pigment applications, and the remainder to paper, leather, and minor applications.

A production cost of 6 $/kg might be accounted for as follows:

Raw materials	$ 1.4
Energy	$ 0.4
Manufacturing	$ 1.6
Administration, research and development	$ 1.6
Servicing fixed and working capital	$ 1.0

Table 3. World dye and pigment production, 10^3 t∗

Year	Western Europe	United States	USSR, Eastern Europe, China	Japan	Others	Total
1938	110	37	35		28	210
1958	112	80	127		27	346
1974	300	138	200	68	44	750

∗ 1 t of dye colors 41 700 men's suits; 1 t of pigment colors 16 600 VW automobiles [24]

Raw materials cost is of course largely outside the manufacturer's control. This cost increases if late-stage intermediates are used, but with a compensating reduction in manufacturing and other costs.

1.6. Environment, Ecology, and Toxicology

Environment, ecology, and toxicology are of increasing importance for manufacturers and users of dyes. Environmental considerations are of major importance in choosing new plant sites and are sometimes economically restrictive to existing operations.

Apart from the legal restrictions, which vary from country to country, on the discharge of acid, alkali, and color, there are increasingly stringent limitations in most developed countries on toxic metals (Hg, Cd, Cu, Ni, Pb, Zn, and Cr), lipophilic aromatic amines, and polychlorobiphenyl compounds (PCBs). Effluents are monitored for pH, biological oxygen demand (BOD), chemical oxygen demand (COD), and total organic carbon (TOC). Dyes are not readily biodegradable and make little contribution to BOD. Some form of adsorption or chemical treatment is often employed to minimize visible color for aesthetic reasons.

Accurate data on colorants discharged to the environment are not available, but estimates suggest a 1 – 2 % loss in production and a 1 – 10 % loss in use [25]. Factories may require some form of adsorption or sewage treatment.

Restrictions on effluents are increasingly important in process development for new products and new plants. The trend is toward process recycling and the incorporation of a detoxifying or neutralizing stage.

The Ecological and Toxicological Association of the Dyestuffs Manufacturing Industry (ETAD) was formed in 1974. The 28 member companies represent > 80 % of worldwide dye manufacture (excluding Comecon countries and China); the two main objectives of the association are as follows:

1) Coordinate and unify the efforts of manufacturers of synthetic dyes and pigments to minimize any possible damage to the environment that arises from the use and application of these products and to provide the best possible practical protection for users and consumers
2) Aid and cooperate with government departments and agencies and any other public institution concerned with the ecological and toxicological impact of these products [26]

The principal legislative acts dealing with ecological and toxicological requirements are the 6th Amendment on dangerous substances in the EEC and the Toxic Substances Control Act (TSCA) in the United States. Both laws distinguish between existing chemicals and "new chemicals" and require the preparation of an inventory and the notification of new chemicals [27].

2. Color and Structure

The correlation between structure and color has always been important in the understanding of organic compounds [28], [29].

The development of quantum theory led to quantitative treatment of these correlations but not to a direct relationship between color and constitution. Instead, the theory linked energy differences between ground and excited states with spectra absorption maxima, as shown in Section 2.3. These absorption spectra are determined in solution, and consequently such correlations, are applicable mainly to dyes, with

only limited value for pigments, which are soluble in very few solvents. The energy acquired by photon absorption is subsequently released, usually as heat, i.e., molecular vibrations. In the present context, however, the release of energy as visible-light emission is more important since it influences the color of fluorescent colorants. In Section 2.4 the two possible emission mechanisms, fluorescence and phosphorescence, are discussed which are important for commercial products (→ Optical Brighteners; → Fluorescent Dyes). In Section 2.5, two examples are given of the correlation between structure and light absorption that demonstrate the success of modern molecular orbital methods. These methods have shed light on the blue color of indigo and the influence of structure on the light absorption of the largest class of industrial dyes (→ Azo Dyes). The effect of substituents on the absorption spectra of aromatic systems is outlined in Section 2.6.

Reflection spectra in the solid state are not important industrially or in theoretical investigations of dyes. Such spectra are, however, extremely important in the application of pigments. Crystal modifications of the same chemical compound may be very different in color. Little, however, is known about correlations between chemical structure and reflection spectra of pigments (see Chap. 3; → Pigments, Inorganic and → Pigments, Organic).

2.1. Basic Principles of Color

Color vision is based on physical, chemical, physiological, and psychological processes. The part of the electromagnetic spectrum visible to humans is the range of wavelengths between 400 and 700 nm. Light can be absorbed completely, partially or not at all by gases, liquids, or solids. The unabsorbed light can be reflected at the surface of liquids or solids or can be transmitted through gases, liquids, or transparent or translucent solids. Light can reach the human retina by direct emission from a source and by reflectance and transmission. Wavelengths between 400 and 700 nm initiate a photochemical reaction followed by light-independent reactions in the light-sensitive pigments of the retina. This process results in visual perception by a transfer of information from the eye to the brain.

This Section treats simple optical concepts as the basis for the correlations between chemical structure and light absorption. Colorimetry has become important in the dyeing of textiles, plastics, and paper. Colorimetry is based on the neurobiological processes in the eye and the brain and is discussed in Chap. 3.

If visible electromagnetic rays, with energy distribution corresponding to sunlight, are subjected to complete and diffuse reflection by a solid, that solid appears *white* to the human eye. On the other hand, if the solid absorbs all the light, it appears *black*. If it absorbs a constant fraction of light in the entire range between 400 and 700 nm, it appears *grey.* White, grey, and black are called *achromatic* colors and are characterized by a constant absorption between 400 and 700 nm (Fig. 1). In contrast, solids having *chromatic colors* show one or more bands, i.e., absorption maxima and minima, in the visible spectrum. If an absorption band is located in the part of the visible spectrum with short wavelengths (400 – 430 nm), that part of the incident light is absorbed. The rest of the light is reflected and the solid appears yellow. Similarly, absorption bands at 430 – 480, 480 – 550, 550 – 600, and 600 – 700 nm yield *orange, red, violet, and blue* colors, respectively (Fig. 1). *Green solids* have absorption maxima at 400 – 450 and 580 – 700 nm. Simple inspection does not distinguish between a green color originating from one dye with two absorption maxima and a mixture of a blue and yellow dye.

The use of two or more different dyes to achieve a certain hue always leads to duller shades than those given by a single dye of the required color. Such a combination is called a *subtractive* mixture. In the ultimate case, black is obtained by "subtraction" of all parts of the visible spectrum. The color of a solution can be explained similarly in terms of light absorbed and transmitted (rather than reflected) by the constituents.

In contrast to these subtractive processes, when light from different sources combines so as to match the relative intensities of sunlight, an impression of colorless (white) results. Such a combination is called *additive.*

For the perception of color by the eye, both the position and the shape of the absorption band are important. Narrower and sharper bands give purer and more brilliant hues. The spec-

Figure 1. Schematic representation of the light absorption of colored solids

—— chromatic colors

Figure 2. Absorption spectra of Indigo in $CHCl_3$, (– – –), Michlers Hydrol Blue in water (– – – – –), and Malachite Green in water (———). From [2], Figs. X.7 and XI.5.

tra of two blue dyes and one green dye are shown in Figure 2. Indigo (C. I. Vat Blue 1) [*482-89-3*], is the most important of all dyes from a historical standpoint (Chap. 1). It is applied mainly to cotton denim (blue jeans), producing a rather dull, slightly reddish blue (navy blue). The dullness is due to the broad band at 580 – 600 nm (half-width ca. 100 nm) and a very weak second band in the 400 – 520 nm region (not visible in Fig. 2). The spectrum of Michler's Hydrol Blue [*14844-71-4*] is characterized by a single narrow band in the visible spectrum (λ_{max} = 647 nm; half-width ca. 50 nm). Therefore, its color is brilliant. The third spectrum, that of Malachite Green (C. I. Basic Green 4) [*569-64-2*], is characterized by two bands in the visible spectrum. In contrast to indigo, they are narrow (λ_{max} = 621 and 427 nm; half-widths 60 and 40 nm, respectively). This combination is seen as green. The absorption of indigo is weaker than that of the two other dyes (low extinction coefficient ε).

Contrary to general belief, in many cases it is not possible to predict the colors of solutions or solids from their spectra. The eye is not equally sensitive to all parts of the spectrum; as a result, color perception is governed not only by the position and the area, but also by the *shape* of the absorption band. Furthermore, the sensitivity of the eye is not the same for day or photopic vision (using cones in the retina as photoreceptors) and for night or scotopic vision (using the more sensitive retina rods). Day vision is most sensitive at 555 nm.

1

The perceived color of the azo dye **1** is illustrative. The absorption spectrum in weakly acidic solution shows a sharp maximum at 500 nm ($\varepsilon = 25\,000$ L mol^{-1} cm^{-1}). In alkaline solution, dissociation of the hydroxyl group gives the naphtholate ion with a broad absorption maximum at 478 nm ($\varepsilon = 14\,000$ L mol^{-1} cm^{-1}); this band extends to 700 nm (Fig. 3).

These absorption maxima would suggest an orange-red color in acid solution and a yellowish-orange hue in alkaline solution. The observed color change, however, is from orange to dull wine-red.

The utility of a colored compound depends not only on the position of the absorption band, but also on its intensity, which is given by the Lambert – Beer law:

$$\log \frac{I_0}{I} = E = \varepsilon d c \qquad (1)$$

where

I = intensity
E = extinction
d = cell length, cm
c = concentration, mol/L
ε = extinction coefficient, L mol^{-1} cm^{-1}

The ε-values of industrial dyes range from less than 10^4 to more than 10^5 L mol^{-1} cm^{-1} (Fig. 2). Dyes with high molar extinction coefficients (e.g., triarylmethine dyes $\varepsilon \geq 100\,000$) are economically efficient. Conversely, anthraquinone dyes are expensive to use because manufacturing costs are high and extinction coefficients are low. The ε-values of anionic and disperse anthraquinone dyes (→ Anthraquinone Dyes and Intermediates) range from 8000 to 18 000. Vat dyes have still lower extinction coefficients; Indanthrone [*81-77-6*] has $\varepsilon = 2600$ in dimethylformamide for $\lambda_{max} = 610$ nm [30]. As shown in Figure 2, indigo also has a low extinction coefficient ($\varepsilon = 12\,000$ in chloroform).

In industrial research, many colored compounds are prepared by varying the substitution on the same basic structure. The effects of such changes are seen schematically in Figure 4. Shifts of the absorption maximum to longer and shorter wavelengths are called *bathochromic* and *hypsochromic* shifts, respectively. Increases and decreases in extinction coefficients (absorption) are termed *hyperchromic* and *hypochromic* shifts, respectively.

Figure 4. Designations of wavelength shifts and changes of extinction of absorption bands

2.2. Empirical Correlations

Correlations between chemical structure and color began to be studied in the early days of dye chemistry. Graebe and Liebermann recognized that all dyes contain conjugated double bonds [31]. The first comprehensive theory was developed by Witt [32] and has been the basis of most subsequent investigations. Witt postulated that color is due to the presence of groups called *chromophores,* which must be linked to the system of conjugated double bonds. Potential chromophores create color if

Figure 3. Visible spectra of dye **1** in acidic (——) and basic solution (– – –).

auxochromic groups are present. Some chromophores have been classed as antiauxochromes [33–35]. With the later development of electron theory, it became apparent that auxochromes are electron donors ($-NH_2$, $-OH$, $-O^-$, etc.), antiauxochromes are electron acceptors, and chromophores are linear or cyclic systems of conjugated double bonds. An assembly of these entities is sometimes called a *chromogen.*

König studied the influence of the length of the conjugated chains in polymethine dyes (**2**, n = 0, 1, 2, . . .) on the wavelength of the most bathochromic absorption band [36].

2

Dyes of type **2** were seen to support the so-called oscillation hypothesis of color that was proposed by von Baeyer [37]; this was based on the Kekulé benzene structure, which has been generalized by Robinson et al. [38] and Ingold and Ingold [39]. Empirical chemical theories of color have been reviewed [28], [29], [40–42].

The development of quantum theory in the 1920s provided a new understanding of chemical bonds and electronic spectra [43], [44].

2.3. Quantum Chemical Methods

As mentioned earlier, color is created by the absorption of electromagnetic radiation of wavelength between 400 and 700 nm. The energy of the light absorbed by the molecule promotes an electron to a higher energy level. This energy difference corresponds to 170 – 300 kJ/mol for visible light and 300 – 12 000 kJ/mol for ultraviolet light; the same absorption mechanism produces electronic spectra in both cases. Light of longer wavelength (e.g., infrared, of 7 – 500 μm) is, on the other hand, not sufficiently energetic to excite electrons, but only causes molecular vibrations.

A real understanding of electronic spectra requires knowledge of the energy of the ground states and excited electronic states of the absorbing molecules and ions. According to the Einstein – Bohr frequency condition (Eq. 2), the energy differences ΔE between these states are proportional to the frequency ν or wavenumber and inversely proportional to the wavelength λ of the absorbed light.

$$\Delta E = h\nu = \frac{hc}{\lambda} \tag{2}$$

With h being Planck's constant and c the speed of light.

In the three-dimensional wave mechanical model of electron distribution the electron orbits

in the Bohr model are replaced by orbitals, i.e., distribution functions of single electrons. The Schrödinger equation (Eq. 3) describes the motion of an electron of mass m and potential energy U as a function of the Cartesian coordinates x, y, and z, the total energy E, and the eigenfunction ψ; ψ^2 is a measurable quantity related to the electron density.

$$\frac{\delta^2\psi}{\delta x^2}+\frac{\delta^2\psi}{\delta y^2}+\frac{\delta^2\psi}{\delta z^2}+\frac{8\pi^2 m}{h^2}\left[E-U\left(x,y,z\right)\right]\psi=0 \quad (3)$$

A closed solution of the Schrödinger equation is possible only for extremely simple systems. Multielectron systems present in diatomic molecules are reduced to one-electron systems by approximation methods.

The *valence bond (VB) method* was first applied to the hydrogen molecule. The bonding effect of its electron pair is ascribed to an exchange interaction of one unpaired electron in an atomic orbital of one of the hydrogen atoms with the unpaired electron of the other atom. Thus, the two electrons are indistinguishable and can exchange positions. The wave mechanical computation shows that this process corresponds to a stabilization of H_2 relative to 2 H Extreme distributions of electrons in VB representations are called limiting structures (for the related resonance theory, see Section 2.5).

Figure 5. Formation of H_2 by the molecular orbital (MO) approximation; energy diagram (A) and form of the σ and $\sigma*$ MOs of the hydrogen molecule (electron densities, B)

In the *molecular orbital* (*MO*) *method*, the molecular wave functions (MOs) are formed by a linear combination of the atomic wave functions (AOs) of the atoms in the molecule (LCAO-MO, linear combination of atomic orbitals). Each molecular orbital formed can accommodate two electrons with opposite spin (Pauli principle). In the case of H_2, the eigenfunctions (wave functions) of the two atomic orbitals are added with the same sign to produce the bonding (or occupied) MO and with opposite sign to obtain the nonbonding (unoccupied) MO (see Fig. 5). In the ground state, both electrons are in the bonding MO. Electromagnetic energy (light) is absorbed by this molecule if the energy of the light is equal to the energy difference ΔE between the occupied and the unoccupied molecular orbitals. In the case of H_2, the two 1s molecular orbitals that are involved are denoted by σ and $\sigma*$; the H – H bond of the H_2 molecule in the ground state is a σ bond.

The energy levels of the bonding orbitals decrease as the atomic orbital overlap increases. This overlap is, therefore, the cause of bond formation in the MO model.

The absorption of light by H_2 occurs in the far ultraviolet ($\lambda = 160$ nm). The high absorption energy for this $\sigma \rightarrow \sigma*$ transition is also in agreement with the fact that in more complex molecules excitation of σ electrons requires high-energy photons.

In this excited state, since the electrons no longer occupy the same molecular orbital, the restriction on their spins that is imposed by the Pauli principle no longer applies; there are, therefore, two excited states, the singlet and the triplet state, with anti-parallel (↓↑) or parallel (↑↑) spins of the two electrons, respectively. The triplet state, which is important with respect to phosphorescence and photochemical reactivity, has a lower energy than the related singlet state. In compounds that contain elements of the second and higher rows of the periodic table, p atomic orbitals must be considered in addition to s orbitals for σ bond formation. These s and p orbitals can be combined to form hybrid orbitals; the method of combination determines the geometry of the molecule. The most characteristic types of s-p hybridization are sp^3, i.e., the combination of one s and three p orbitals (tetrahedral, specific for aliphatic hydrocarbons), sp^2 (trigonal, typical for olefins and aromatic com-

pounds), and *sp* (digonal, acetylenes). In sp^2 hybridization, only two *p* electrons (p_x and p_y) are used together with the *s* electron. The third *p* orbital (p_z) does not take part in hybridization. It is used to form the π orbital. Similarly, with *sp* hybrids, the p_y and the p_z orbitals are used for the formation of two π orbitals.

In ethylene there are only two π electrons; their combination in an MO is formally analogous to the treatment of the two *s* electrons in H_2 discussed previously (Fig. 5 A). A division is obtained between an MO occupied (in the ground state) by both electrons (π MO) and an unoccupied higher energy MO ($\pi *$).

Electrons in these π MOs are less strongly bonded and can be more easily excited into $\pi*$ orbitals by absorption of light of longer wavelength, i.e., lower energy. This explains the rule of Graebe and Liebermann (Section 2.2) that unsaturated compounds with double bonds absorb light at longer wavelengths than saturated compounds, especially if the double bonds are conjugated [31].

Figure 6. The π orbitals of benzene

The properties of *benzene* do not correspond to those of the hypothetical cyclohexatriene. The most bathochromic absorption band of benzene is at 250 nm. The electron distribution follows from molecular orbital considerations. As with ethylene, π orbitals overlap, but with the hexagonal symmetry not only do three pairs of adjacent π orbitals overlap, but also all six π orbitals, resulting in delocalization of the six π electrons over all six C–C bonds. The MO calculations by Hückel in 1931 show that the second and third bonding orbitals possess the same energy (*degenerate MOs*). The two lower antibonding orbitals are also degenerate. The energy levels of these orbitals are shown in Figure 6, as calculated by the simplest MO approximation method (Hückel MO or HMO) [45].

Here the so-called Coulomb integral α serves as a reference energy level for the sp^2 hybridized carbon atom, corresponding approximately to the ionization potential of an electron in a $2p$ atomic orbital. The resonance integral β is a measure of the interaction between two orbitals; it is approximately proportional to the overlap integral *S* and with aromatic hydrocarbons amounts to 74–83 kJ/mol. The energy 2β is termed the mesomeric or delocalization energy of benzene, and is responsible for its stability.

Hückel demonstrated that this particularly strong stabilization occurs only in homo- and heterocyclic compounds that have $(4n+2)\pi$ electrons in the perimetric ring system (Hückel rule). As the investigation of annulene systems showed, it is not fundamentally important whether they are mono- or polycyclic systems when $n = 1, 2, 3, \ldots$ (etc.). The cycloheptatrienylium cation, which Hückel predicted to be stable (tropylium ion, C_7H_7), was first prepared by Doering in 1956, confirming the usefulness of quantum theory in organic chemistry.

Heterocyclic compounds also possess benzenoid characteristics if they have $(4n + 2)$ overlapping π orbitals. This is true for pyridine and pyrimidine. Thiophene and pyrrole are also aromatic because the lone pairs at S and N, respectively, are in p_z orbitals and overlap with the π electrons of the carbon–carbon double bonds.

When an aromatic compound carries a group with π orbitals e.g., NO_2 or COOH on an aromatic carbon, both π electron systems overlap, leading to new bonding and antibonding electronic states. This also occurs with atoms that have lone pairs of electrons (e.g., OH or NR_2) in *p* orbitals which, for geometrical reasons, can also overlap with the aromatic π orbitals. This,

however, is not the case with the lone pair on nitrogen in pyridine. Both electrons occupy an $sp_x{}^2$ hybrid atomic orbital located in the plane of the six-membered ring perpendicular to the *p* orbitals of the aromatic π system. Therefore, interaction between this lone pair and the π system is minimal.

A molecular electronic spectrum exhibits a number of absorption bands of widely differing intensities which are partly superimposed. In principle, *one* particular electron transition corresponds to each band. However, the origins of these bands are often not clear since simultaneous changes in the vibrational states are superimposed on the electron transitions.

The essential types of energy levels are shown in Figure 7 in the simplest form for two types of compounds: a compound A with a pair each of *p,* π and *n* electrons, and a compound B with one pair of *p* and *n* each but with two pairs of conjugated π electrons.

Figure 7. Designation of molecular orbitals and representation of energy levelsA: for a molecule with one *p,* one π, and one *n* electron pair
B: for a molecule with one *p* and two conjugated π electron pairs (number of *s* electrons not specified)

In both cases only one occupied σ and one unoccupied $\sigma*$ level are shown although all real compounds have more *s* electrons. These are, however, not important for the present discussion.

For compound A the transition of an *n* electron from the nonbonding orbital (*n*) to the antibonding $\pi*$ orbital requires the least energy. The $n \rightarrow \pi*$ transition, therefore, gives rise to an absorption band at a longer wavelength than the $\pi \rightarrow \pi*$ transition. In the case of compound B, the π_1 and π_2 levels are split (nondegenerate). Therefore, for the given example the band at the longest wavelength corresponds to a $\pi \rightarrow \pi*$ transition. Not all transitions, however, go to antibonding levels: in arylmethine dyes transitions to nonbonding excited states are important.

As shown above for benzene, the HMO method takes into account only the π orbitals; σ orbitals, their interaction with π orbitals, and interactions between two or more π electrons are neglected. Therefore, the HMO method can be applied to simple aromatic compounds, e.g., disubstituted benzenes, only in a very restricted way by a suitable choice of empirical parameters. In the so-called MIM (molecules-in-molecules) version of the HMO method, the only changes calculated in relatively complex molecules (which relate to the known spectra of subsystems) are those that occur when these subsystems are coupled to the whole molecule.

Until 1937, quantum mechanical calculations sought to determine the energies of ground states of molecules, particularly for compounds such as benzene. However, in that year, recognition of the importance of the excited states of a molecule for light absorption allowed the calculation of the absorption bands of a number of unsaturated hydrocarbons by early MO methods [46]. Shortly afterward PAULING applied the VB method [47]. Whereas the chemical theories discussed in Section 2.2. were concerned mainly with dyes of industrial importance, quantum mechanical methods started with very simple systems.

The free electron model (FE-MO theory) was particularly important for interpreting the electronic spectra of complex dyes [48–53]. Simple calculations based on this model show good agreement with experimental spectra, particularly for polymethine dyes [54–57].

With this model the wave functions of the π electrons are treated as waves in a box corresponding to the dye molecule or ion; in the simplest case, the box is one-dimensional and

as long as, for example, an all-*trans* polymethine chain. Stationary states are then characterized by standing waves; the length of the box (L) in which the electron moves is equivalent to an integral multiple ($n = 1, 2, 3, \ldots$) of the half-wavelength λ ($L = n\lambda/2$). The energy levels ε_n corresponding to these waves are occupied from $n = 1$ upward with 2 π electrons each and correspond to molecular orbitals. The energy difference ΔE between the highest occupied orbital E_{HOMO} (HOMO = highest occupied MO [58], [59]) and the next orbital above, i.e., the lowest unoccupied orbital E_{LUMO}, yields the $\pi \rightarrow \pi *$ transition energy with the aid of the physical constants h and m (mass of the electron) and the length (L) of the system of conjugated double bonds of the polymethine dye (Eq. 4). With the Einstein – Bohr frequency condition (Eq. 2), ΔE yields the frequency of the absorption band; the acronyms HOMO and LUMO were proposed by Fukui in the frontier orbital method [31], [32].

$$\Delta E = E_{\mathrm{HOMO}} - E_{\mathrm{LUMO}} = \frac{h^2}{8mL^2}\left(n^2_{\mathrm{HOMO}} - n^2_{\mathrm{LUMO}}\right) \tag{4}$$

In Fig. 8 A, the energy levels $\varepsilon_n = 1$, 2, 3, 4, and 5 of Equation (4) are given with the respective waves for the trimethine cation $R^2NCH{=}CHCH{=}N^+R_2$. They are compared with the energy levels of the molecular orbitals produced by the linear combination of atomic orbitals in the HMO method (Fig. 8 B). Figure 8 C shows the corresponding view as seen from above. The size of the circles is proportional to the LCAO-MO coefficients of the atomic orbitals. The HMO and FE methods are compared in Figs. 8 B and 8 C. For more complex π electron systems, the simple FE-MO model does not correspond well to experimental spectra; such systems can be handled by two- and three-dimensional FE methods. The FE-MO model is clearest for didactic purposes.

The energy of each MO is determined not simply by a single-electron configuration, as assumed in HMO and FE-MO methods, but by the interaction of several such configurations. Electron – electron interaction and configuration interaction (CI) are taken into account for π-electrons in the Pariser – Parr – Pople (PPP) method [60], [61]. This method has given successful calculations of the spectra of colorants including those with secondary absorption bands at shorter wavelengths.

The $\pi \rightarrow \pi *$ transitions are also influenced by σ electron distributions and may mix with certain $\sigma \rightarrow \sigma *$ transitions. This is taken into account in the semiempirical all-valence electron methods, the so-called CNDO, MINDO, INDO, and related approximations (CNDO, MINDO, INDO = complete, modified intermediate, and intermediate neglect of differential overlap, respectively). They are useful for small π electron systems, but the improvement over PPP for larger colorants is not significant.

The PPP method reproduces the main features of various classes of chromophores, and the calculated absorption wavenumbers differ by not more than 3000 cm^{-1} from the observed absorption maximum ([29], p. 7). This is ca. 20 nm in the 250-nm region, but more than 100 nm in the visible 600-nm region. Closer agreement can be obtained within narrow structural changes by optimizing the parameters used for the calculations.

The PPP method has been applied by Griffiths to practically all classes of dyes [28], [40, 41], [62, 63].

In principle, the intensity of absorption is also obtainable by MO methods. The extinction coefficient is a function of the shape of the orbitals and of the degree of overlap, i.e., of the so-called transition dipole moment M, which has the character of a vector. In general, this has different magnitudes along the three Cartesian coordinates (x, y, and z in Eq. 3). This explains the dichroism of dye crystals in polarized light (see Section 2.6) or of dyes dissolved in nematic phases of liquid crystals or stretched polymer sheets [64]. The extinction coefficients depend on the plane of polarization.

The transition moment contains the product of the two overlapping orbitals, the so-called overlap densities $\Phi_m \Phi_n$. This product is a measure of the localization of the two orbitals in the same part of the molecule and, therefore, describes the probability of an electronic transition from one orbital to another. The molar extinction coefficient of the absorption maximum ($\varepsilon_{\max}$) is related to the so-called oscillator strength (f) via the square of the transition moment (M^2) and the wavenumber ($\tilde{\nu}$) of that transition (Eq. 5); $\int e_{\max} \mathrm{d}\tilde{\nu}$ corresponds to the area of the band, and $\Delta\tilde{\nu}_{1/2}$ is the width of the band at half-height:

Figure 8. The π MOs of the trimethine cation $R_2NCH{=}CHCH{=}N^+R_2$ in the free electron (FE) model (A) and in the HMO model (B) and (C)
Reproduced with permission of M. Klessinger [56]

$$f = 4.703 \times 10^{29} \tilde{\nu} M^2 = 4.32 \times 10^9 \int \varepsilon_{\max} \mathrm{d}\tilde{\nu}$$
$$= 4.32 \times 10^9 \varepsilon_{\max} \Delta\tilde{\nu}_{1/2} \quad (5)$$

In this case the band is assumed to be symmetrical (Gaussian curve). However, this is rarely the case with electronic absorption bands. Unsymmetrical absorption bands result from the superposition of vibrational processes upon electronic transitions in the ground and excited states, as well as from interactions with neighboring molecules (solvatochromism).

2.4. Fluorescence and Phosphorescence

An excited molecule or ion can release energy in several ways:

1) Radiationless transition as internal conversion or intersystem crossing (heat formation)
2) Emission of radiation (fluorescence and phosphorescence)
3) Photochemical reactions

Processes of types 1 and 2 are represented in the Jablonski diagram (Fig. 9), a scheme of the essential energy levels. The lowest vibrational energy levels of the electronic states are indicated by thick horizontal lines; other horizontal lines represent higher vibrational levels. A molecule (or ion) in the ground state S_0 is brought to an excited singlet electronic state, S_1 or S_2 (or higher states S_j) by absorption of light. Radiationless transitions are shown by wavy lines. Vibrational deactivation (indicated by vertical wavy lines) leads to the lowest vibrational level of the respective excited singlet electronic state or to lower singlet states. Intersystem crossing (indicated by horizontal wavy lines) leads to triplet states. Radiation from the lowest vibrational level of the excited state S_1 to any of the vibrational levels of the ground state is called *fluorescence.* Radiation from the lowest triplet state T_1 to the ground state is called *phosphorescence.*

Photochemical reactions (e.g., rearrangement, dissociation, dimerization, photoaddition, or reaction with neighboring particles) arise most often from triplet states of lifetimes between 100 ns and 10 s. The lifetime of excited singlet states is normally too short for chemical reactions (1 – 100 ns).

Figure 9. Jablonski scheme
Reproduced from Ciba-Rundschau 1973, no. 1, with permission

With the exception of phosphorescence, all radiation processes are very rapid, with first-order rate constants of the following orders of magnitude:

Light absorption	$10^{15}\ s^{-1}$
Vibrational relaxation	$\geq 10^{12}\ s^{-1}$
Fluorescence	$10^{6} - 10^{9}\ s^{-1}$
Intersystem crossing	$10^{-1} - 10^{5}\ s^{-1}$
Phosphorescence	$10^{-2} - 10^{4}\ s^{-1}$

As seen from Fig. 9, absorption normally occurs from the lowest vibrational level of the electronic ground state and leads to one of the higher vibrational levels of an electronic excited state. Fluorescence arises in most cases from the lowest vibrational level of the first excited state (S_1) and ends in one of the higher vibrational levels of the ground state. Therefore, the fluorescence spectrum, in ideal cases, is a mirror image of the absorption spectrum, but shifted to higher wavelengths (Stokes shift).

For phosphorescence to occur, molecules primarily excited to the S_1 singlet state must revert to the lowest level of their triplet manifold (T_1) by radiationless intersystem crossing. From T_1 the molecules can slowly emit radiation (phosphorescence) or they can return to the S_0 level without emission by intersystem crossing. Phosphorescence spectra are also usually shifted to longer wavelengths much more than fluores-

cence, because the energy of the triplet level T_1 is usually below that of the singlet S_1.

Most fluorescent organic compounds are characterized by a rigidity of structure which prevents the energy of the excited states from being lost by torsional vibration. The classic example is fluorescein [*2321-07-5*] (C.I. Acid Yellow 73, **4**), which is highly fluorescent. In contrast, phenolphthalein [*77-09-8*] (**3**) shows no fluorescence because its excited state loses energy by internal conversion (vibrations of the benzene rings), a process that is prevented in fluorescein by the ether link between two of the aromatic rings.

3

4

An interesting example of wavelength shifts is shown by the three vinyl polymethine dyes (**5**) ($m = 1$, 2, and 3). They show a bathochromic shift of the absorption (abs.) maximum for $m = 1$, 2, and 3 from 500 to 526 and 544 nm, respectively. The shifts in the fluorescence (fl.) maxima, however, are much larger. The difference λ_{max} (fl.) $-$ λ_{max} (abs.) for $m = 1$, 2, and 3 is 115, 175, and 245 nm, respectively [65]. This effect is probably due to larger energy differences between the excited singlet and triplet states in that sequence.

5

The fluorescence efficiency of a compound is related to the quantum yield, i.e., the fraction of the absorbed light energy that is emitted in fluorescence.

Although dyes and pigments that fluoresce in the ultraviolet and in the infrared ranges are known, most fluorescent colorants absorb and fluoresce in the visible spectrum (→ Fluorescent Dyes). Dyeings with such dyes appear brighter. They are used for fibers, plastics, as active media for dye lasers (→ Laser Dyes), and for biological staining (→ Stains, Microscopic). Optical brighteners are compounds whose most bathochromic absorption band is in the near-ultraviolet range and whose fluorescence is visible. They are used for increasing the whiteness of textiles, plastics and soaps (→ Optical Brighteners).

2.5. Quantitative Treatment of Light Absorption

For azobenzene and its derivatives, the assignment of the absorption band of longest wavelength (most bathochromic) and all other visible and near-ultraviolet bands (down to 210 nm) shows the importance of the various electronic transitions in simple compounds. *trans*-[*17082-12-1*] and *cis*-[*1080-16-6*] azobenzene (**6** and **7**) have in addition to σ electrons two times six π electrons in the two aromatic rings, two π electrons in the azo group, and two electron lone pairs on each nitrogen atom. Various $n \rightarrow \pi*$ and $\pi \rightarrow \pi*$ transitions can be expected.

6

7

The absorption spectra of *cis*- and *trans*-azobenzene have been successfully interpreted by MO methods [29, pp. 46 ff]. Figure 10 shows the molecular orbital energy diagram of azobenzene with the three highest occupied and the three lowest unoccupied π orbitals and the nonbonding orbitals of the nitrogen lone pairs [66]. The last are degenerate in two orbitals (n_s and n_a), which are present in 4-aminoazobenzene derivatives.

The weak band at the longest wavelength in the visible spectrum of *trans*-azobenzene ($\lambda = 450$ nm, $\varepsilon = 463$; see Fig. 11) and *cis*-azobenzene ($\lambda = 430$ nm, $\varepsilon \approx 1500$) is due to the $n_s \rightarrow \pi_1*$ transition. The strong second bands (*trans* 330 nm, $\varepsilon = 17\,000$; *cis* 280 nm, $\varepsilon \approx 5100$, shoulder) are due to $\pi_1 \rightarrow \pi_1*$ transitions. Since *cis*-azobenzene is nonplanar, n and π-orbitals mix. This is the reason for the higher intensity of the $n_s \rightarrow \pi_1*$ band and for the weaker $\pi_1 \rightarrow \pi_1*$ absorption. The highest energy processes in the region 230 – 240 nm are due to the $\Phi \rightarrow \Phi*$ transitions; i.e., they are regarded as being localized

in the benzene rings. This is probably the reason that this part of the benzylideneaniline spectrum is similar to azobenzene and stilbene (Fig. 11). Of course, stilbene has no $n \rightarrow \pi *$ transition.

In spite of its orange color, azobenzene is not used as a dye because its molar extinction coefficient in the visible region is too small for practical purposes ($\varepsilon = 450$). If an electron-releasing group with lone pairs (e.g., dimethylamino) is introduced in the 4-position, a significant hyperchromic change results. The extinction coefficient of the longest wavelength band ($\lambda_{max} = 408$ nm) is then 27 500 (in 95 % ethanol) as in Dimethyl Yellow, C.I. Solvent Yellow 2 [*60-11-7*], a dye in the industrial sense. An additional electron acceptor group, e.g., NO_2, in the 4′-position (compound **8**) produces a definite bathochromic shift ($\lambda = 478$ nm, $\varepsilon = 33\,100$ in 95 % ethanol). However, these intense visible bands correspond not to the $n_s \rightarrow \pi_1*$ transition, but to the $\pi_1 \rightarrow \pi_1*$ transition of azobenzene. This is shifted from the ultraviolet to the visible spectrum by the influence of the substituents. Negligible $n_s \rightarrow \pi_1*$ and, presumably, weaker transitions are superimposed.

Azobenzene, 4-dimethylaminoazobenzene, and 4-dimethylamino-4′-nitroazobenzene [*2491-74-9*] (**8**) illustrate the rules of Witt [5] and Dilthey and Wizinger [6] (see Section 2.2): The absorption shifts are created by adding an auxochrome (NR_2) and an antiauxochrome (NO_2) to a chromophore.

In resonance theory, which is a qualitative version of the valence bond theory (VB, see Section 2.3), it is assumed that increasing numbers of resonance structures correspond to easier excitability of electrons, i.e., longwave absorption. Thus, it is possible to write an increasing number of polar resonance structures for azobenzene, Dimethyl Yellow, and 4-dimethylamino-4′-nitroazobenzene. Apart from the fact that the choice of resonance structures is largely arbitrary, quantum chemical treatment shows that the assumption of equal distribution among resonance structures in the ground and excited states is, in many cases, incorrect. 4-Dimethylamino-4′-nitroazobenzene (**8**) is a typical example, which can be represented as a hybrid of the three structures **8a**, **8b**, and **8c**, as well as many other structures.

The PPP method gives in the ground state a partially positive charge (+0.327) for the amino group and partially negative charges for the azo and nitro groups (−0.206 and −0.131, respectively). This corresponds qualitatively to the resonance structures, but indicates nothing about charge distributions in the excited states. According to PPP calculations the charge densities in the first excited state at the three sites mentioned are drastically different from those in the ground state, e.g. the charge density at the nitro group is not negative, but positive [63]. The electronic excitation could, therefore, be regarded as being associated with the transfer of charge from one site of the molecule to another. Figure 11 shows the absorption spectra of *trans*-azobenzene (**6**) and two iso-π-electronic compounds, *trans*-stilbene [*103-30-0*] (**9**) and *trans*-benzylideneaniline [*538-51-2*] (**10**).

9

10

The similarity of the azobenzene and stilbene spectra (apart from the weak visible band of azobenzene) indicates similar electron transitions. Surprisingly, however, the spectrum of benzylideneaniline, which may be regarded as a

8a **8b** **8c**

Figure 10. The molecular orbital diagram for azobenzene, including the three highest occupied, three lowest unoccupied, and the nonbonding orbitals of the nitrogen lone pairs

Figure 11. Spectra of *trans*-azobenzene (– – --, **6**), *trans*-stilbene (—- - —-, **9**), and *trans*-benzylideneaniline (———--, **10**) (in cyclohexane) [67]

hybrid of the two other compounds, differs considerably from those of azobenzene and stilbene. This is due to twisting around the C – N single bond by 55 °, thus dividing the conjugated system into two weakly interacting π systems. Ring closure of the methine group in **8** to the aniline ring forms the indolenine derivative **11**, which is also a planar molecule with a spectrum very similar to that of *trans*-azobenzene and *trans*-stilbene; the most intensive absorption bands in cyclohexane are $\lambda_{max} = 310$ nm, $\varepsilon = 17\,000$, and $\lambda_{max} = 235$ nm, $\varepsilon = 16\,000$ [67].

A knowledge of changes in charge densities between the ground and excited states helps to explain *solvatochromism,* the effect of a solvent on the color of a dye. Positive and negative solvatochromism should be differentiated, i.e., bathochromic and hypsochromic shifts with increasing solvent polarity. As the interaction of solvent with solute depends on the charges and the dipole moments of the various electron states of the solute molecules, a large change in electron densities causes strong solvatochromism. Experimentally, a bathochromic shift of 38 nm is found for **8** when the solvent is changed from cyclohexane to nitromethane. The spectra of azobenzene and Dimethyl Yellow are less sensitive to solvent changes. If a bathochromic shift is found with increasing polarity of the solvent, the excited state is more polar (and thus stabilized in a more polar solvent) than the ground state. Hypsochromic shifts arise when the ground state is more polar (and more strongly stabilized in a more polar solvent) than the excited state.

Association of two or more dye molecules, or ions, or aggregation of dye particles with other molecules or ions (ion pairs, aggregates, micelles) also changes the electronic spectra in most cases [68], [69].

Indigo [*482-89-3*] (C.I. Vat Blue 1, **12a**) is the most famous natural dye and was the most widely used dye in the world before the appearance of synthetic dyes. The elucidation of its structure by VON BAEYER and its first successful commercial synthesis by HEUMANN were the greatest achievements in color chemistry of the 19th century (see Chap. 1).

a) X = NH
b) X = S
c) X = Se

12

Qualitative and empirical theories were unable to explain either the blue color of this relatively simple molecule or the red color of its S-analogue, thioindigo [*522-75-8*] (**12b**). Consequently, the von Baeyer structure was repeatedly questioned, but was finally verified by X-ray analysis to be **12** [70], [71]. In the solid state, neighboring molecules are strongly hydrogen-bonded, which explains the high melting point (390 – 392 °C) and low solubility.

The spectrum of indigo has been investigated by HMO [72] and PPP methods [73–75]. The basic chromophore of indigo, thio-, seleno- and oxindigo is the partial structure **13**, consisting of a C=C double bond substituted by two donor groups X and two acceptor groups C=Y. This system is called a cross-conjugated or H-shaped chromophore (**13**).

X = NH, S, Se, O
Y = O, (NR)

13

The benzene rings in indigo play only a secondary role, as shown by tetramethylpyrrolindigo (**14a**). In 1963 indigoid dyes and tetramethylpyrrolindigo were the only known examples of H-shaped chromophores.

a) X = NH
b) X = S

14

Subsequent synthetic work produced compounds (**15**), (**16**), and **17**, which contain the n and π electrons of the H-shaped chromophore (**13**), but without the additional π electrons found in indigo, thioindigo, and pyrrolindigo [76–79]. The observed spectra (Table 4) and the similar shapes of the absorption bands corroborate the MO predictions. Additional support is afforded by **18** and **19**, which contain an analogous linearly conjugated system, but without cross-conjugation between the donor S atom and the carbonyl acceptor.

The color of indigo (**12a**) depends strictly on conditions: it ranges from red in the vapor phase (λ_{max} = 540 nm) to violet in a nonpolar solvent, and to blue in polar solvents and in the solid state. Amorphous and crystalline indigo differ significantly in their maxima (650 and 675 nm,

Table 4. The longest wavelength absorption bands (λ_{max}, nm, and in parentheses log ε) of indigo and thio- and selenoindigo (**12.**), cross-conjugated chromophores **15**–**17**, and not cross-conjugated chromophores **18** and **19**

∗ In CCl_4

respectively). These differences probably reflect the influence of inter- and intramolecular hydrogen bonding.

The hypsochromic shift in the cross-conjugated thio series **12b**, **15b**, **16b**, and **17** is mainly due to decreasing planarity of the five- and six-membered rings. The linearly conjugated compounds **18** and **19** no longer show similarity to indigoid dyes.

After dividing **13** into two identical subsystems (by formal splitting of the C=C double bond), perturbation theory (PMO) explains the hypsochromic shift between X=NH and X=S, which is due to −S− being a poorer electron donor than −NH− [75]. The PPP method includes electron interaction, and although it is important for a quantitative description of the indigo spectrum, it does not change the general HMO and PMO results [29, pp. 115 ff], [75].

It is interesting to compare the bathochromic effect of cross-conjugated systems of type **13** (X=NH, Y=O) with those of polymethine dyes **20**and **21**, in which similar donors and acceptors are found at the ends of a linearly conjugated C=C chain (→ Methine Dyes and Pigments). In the case of the merocyanines (**20**), donor and acceptor groups are directly comparable with the respective groups of indigo (**12a**). An absorption band in the range of cross-conjugated systems containing only one C=C double bond is obtained only with a dodecahexaene system (**20b**), i.e., with six conjugated double bonds. Similarly with symmetrical cyanines (**21**), which show the strongest bathochromic shift of all polymethine dyes, at least three conjugated C=C double bonds are necessary to obtain absorption in the indigoid range.

It would seem obvious that a combination of linearly conjugated double bond systems with cross-conjugated compounds should result in further bathochromic shifts. However, this expectation is not fulfilled by the series of compounds **22** and **23** (Table 5) [29, p. 124].

The examples in Table 5 show the difficulty of developing simple qualitative correlations between structure and electronic spectra of π systems.

Table 5. The longest wavelength absorption maxima (λ_{max}, nm, and in parentheses log ε) of vinyl indigo blue dyes , p. 124[29]

	Substituent			
Compound	X	$n = 0$	$n = 1$	$n = 2$
22	NH	615 (4.32)	573 (4.35)	
	S	554 (4.17)	534 (4.36)	532 (4.56)
	Se	573 (4.10)	545 (4.25)	
23	S	450 (4.13)	446 (4.50)	454 (4.67)
	Se	476 (4.17)	463	

These two examples of aminoazobenzene and indigo derivatives demonstrate that three structural characteristics are important for long-wavelength electronic spectra:

1) Linear and cyclic systems of conjugated double bonds
2) Electron donors
3) Electron acceptors

Maximum overlap of the π orbitals of these systems is essential and can be achieved only in coplanar molecules and ions.

2.6. The Influence of Substituents on the Spectra of Aromatic Compounds

The discussion in the preceding Section 2.5 demonstrates that substituents significantly influence the spectra of azobenzene and indigoid dyes.

Simple benzene derivatives and the industrially important quinacridone and anthraquinone dyes show that qualitative rules based on chemical classification of substituents are applicable only within a narrow range; however, their spectra can be interpreted by quantum-mechanical methods.

The spectra of 2-, 3-, and 4-substituted nitrophenols, cyanophenols, and nitro-*N*-dimethylanilines, i.e., benzene derivatives with donor and acceptor substituents, cannot be understood from simple considerations of mesomeric structures. The *o*- and *m*-, but not the *o*- and *p*-compounds absorb very similarly over the whole range above 220 nm, whereas the absorption bands of the *p*-isomers are hypsochromically displaced and different in type. This problem was solved by the molecules-in-molecules (MIM-MO) [80] and PPP methods [81].

The introduction of a further donor (D) into a benzene derivative that already carries an electron acceptor (A) and an electron donor causes the following shifts relative to the 1,4-donor – acceptor compound:

This is called the rule of the distribution of auxochromes, which has been known since 1911. It is corroborated by many examples of industrially important dyes of the azo, anthraquinone, and other classes. The customary concept of mesomeric structures is not able to explain the energy in the excited state, but an MIM investigation gives the correct answer [80].

Examples of the distribution of two donors and acceptors each on benzene are provided by the pigment quinacridone (**24**) and its isomer **25**. The former is reddish violet ($\lambda_{max} = 523$ nm), whereas **25** is yellow ($\lambda_{max} = 436$ nm).

For the assignment of bands to specific transitions, spectra of oriented molecules (dye crystals or dyes adsorbed on stretched polymer films) in polarized light are useful. Dichroism, i.e., different extinctions parallel and perpendicular to the direction of light polarization, is frequently observed. This method settled a long controversy over the spectrum of anthraquinone [82]. The three bands at 320, 270, and 250 nm arise from

three $\pi \rightarrow \pi *$ transitions. The first and third bands are polarized along the axis of the three six-membered rings; the second transition arises from an excitation perpendicular to this axis.

The dichroic character of many dyes, particularly anthraquinone derivatives, has become important for liquid-crystal displays of small computers or watches. Dyes are adsorbed uniformly onto the liquid crystals, which become ordered in an electric field; the effect of dichroism can be used to produce color contrasts.

In summary, it is possible in principle to explain electronic absorption bands quantitatively. It has been stated that "the routine type and reliable calculation of wavelengths and extinctions of any organic compound is possible today" [29] and that "the search for new chromogens need not now depend on serendipity or massive synthetic attack. A pen, paper, an inventive mind and a modest computer can achieve much more, with far greater economy" [63].

At present these statements can be only partly supported. It is insufficient if the extinction maxima, calculated by PPP, are correct within only ca. 100 nm [29, p. 7]. The calculation of oscillator strengths and extinctions is even more crude, and the theories indicate almost nothing about the *band shape* which may be decisive for color (Fig. 3). Future progress is to be expected, however, with the help of faster computers and more precise approximation methods.

Fukui, in his Nobel lecture, emphasized the mutual correlations between theoretical and experimental reaction mechanisms [59]; similar considerations apply to light absorption.

Calculations of dye spectra are much more successful if a generalized set of PPP parameters, limited in number but applicable to all known classes of dyes, is used [62]. The so-called valence-state ionization potential (VSIP) of a bond is the parameter that exerts the largest influence in wavelength calculations. However, although these parameters are related to only one bond, they are very sensitive to the overall structure of the dye [83]. They are therefore not yet the final solution.

The biggest advantage of a quantum-chemical treatment lies perhaps in the comparison of energies of adjacent occupied and unoccupied molecular orbitals, as shown in the free-electron model. A second advantage is the possibility of elucidating the basic structural features of *particular* known colored compounds, as shown for indigo.

3. Color Measurement and Colorant Formulation

The color of a material is governed by the composition of the light reflected by that material into the observer's eye. Dyes modify the color of the substrate because they absorb light in the visible region of the spectrum. Nonwhite pigments also possess this ability, but in addition, all pigments scatter light; however, with dyed materials, the light is scattered by the substrate. The combined effect of absorption and scattering is measured by determining the reflectance factor at each wavelength in the visible region of the spectrum, using a reflectance spectrophotometer. Although reflectance factors completely quantify the color characteristics of the material, these factors do not constitute color measurement because perceived color also depends on the incident light, i.e., the spectral power distribution. In addition, two materials viewed under the same light may appear to have the same color, yet their reflectance curves may be different, a phenomenon known as metamerism.

Color measurement requires the mathematical reduction of the two dissimilar reflectance curves to give the same numerical definition of color; such a method was introduced by the CIE (Commission Internationale de l'Éclairage) in 1931. With minor modifications this is the only method used today. It defines a color by three numbers known as *tristimulus values, X, Y*, and *Z*. These numbers quantify the amounts of three imaginary lights which, if shone onto a pure white surface, would match the color of the material illuminated by a specified source. This method, using real lights, was first conceived by Maxwell in the 19th century.

Tristimulus values are rarely used to specify a color, but are widely used to predict how much of which colorants (dyes or pigments) would be required to produce a color (colorant formulation) and to quantify the perceived difference between materials of similar color (quality control).

3.1. Measurement of Reflectance Factors

The reflectance factor of a given material at wavelength λ is the ratio of amount of light of wavelength λ reflected by the material to that reflected by a perfect reflecting diffuser illuminated in the same manner. The instrument used for this determination is a reflectance spectrophotometer; such instruments plot a reflectance curve or display its digital equivalent.

The first reflectance spectrophotometer sequentially irradiated the specimen and a block that was coated with magnesium oxide (which was the CIE standard of reflectance until 1969) with monochromatic light, the reflection from both surfaces being compared by a photocell [84]. The reflectance factor at each wavelength is expressed as a percentage (0 – 100 scale) although calculations are made on reflectance factors expressed on a 0 – 1 scale.

However, such instruments are not suitable for fluorescent specimens since they are based on the assumption that the incident and reflected light have the same wavelength. If the specimen is fluorescent, the photodetector gives spurious results over a significant region of the spectrum.

When fluorescent brightening agents became widely used in the 1950 s, spectrophotometers needed to be designed that irradiated the specimen with polychromatic light whose spectral power distribution (SPD) resembled that of daylight. The light that comes from the specimen consists of both reflected and emitted light and is passed to the photodetector through a series of interference filters. The SPD of daylight was established by the CIE in 1963 as Illuminant D65, the 65 indicating that its color temperature was ca. 6500 K. The SPD covered the range of 300 – 830 nm, the inclusion of the ultraviolet region being essential when brightening agents were measured. Most modern spectrophotometers attempt to simulate D65, but this has proved to be difficult [85, p. 122].

Figure 12 illustrates a modern spectrophotometer. A pulse of light of 20 – 30 μs duration from a xenon arc passes through a filter, which renders the SPD closer to that of D65, through an integrating sphere to the sample being measured. The light coming from the sample passes to a monochromator, which is a reflecting diffraction grating, and to an array of 17 photodiodes spaced every 20 nm from 380 to 700 nm. A Fresnel prism is then moved over the exit port, and a second pulse of light enters the sphere. The light then falling on the monochromator comes from the sphere wall which acts as a transfer standard. This is known as dual – beam operation; it automatically compensates for the fact that a colored specimen changes the color of the irradiating light. The signals from the 17 photodiodes are electronically processed in parallel, the final output being the reflectance factors at every 20 nm from 380 to 700 nm. Every few hours the instrument is calibrated by measuring the reflectance of a white tile and a black tile, whose reflectances relative to the perfect reflecting diffuser have been determined against standard tiles.

The wall of the sphere contains a port, which permits the inclusion or exclusion of the specular component of the reflected light. This is essential because in the case of nonmetallic specimens, specularly reflected light has not the SPD of diffusely reflected light, but that of the irradiating light. These two viewing geometries are known as total/normal if the port is closed with the material used for the sphere wall and diffuse/normal if it is open and leads to a light trap. Other spectrophotometers irradiate the specimen with a beam of light normal to the surface and view it at 45°, known as 0/45 or vice versa, 45/0. These are primarily intended for the measurement of moving specimens since they minimize the effects of any variations in the distance from the port. Measurements on glossy specimens with 0/45 or 45/0 geometries (which give identical results because of the Helmholtz reciprocity principle) usually lie between those obtained with total/normal and diffuse/normal viewing geometries. Total/normal geometry is preferred for colorant formulation, and diffuse/normal geometry is preferred for evaluating color differences. All of these viewing geometries are defined by the CIE [86].

Most reflectance spectrophotometers also permit insertion of an ultraviolet absorbing filter into the incident beam (not shown in Fig. 12). This enables fluorescent specimens to be recognized, as the reflectance curves with and without the ultraviolet component are different. It also permits the effectiveness of fluorescent brightening agents to be measured.

3.2. Calculation of Tristimulus Values

A reflectance curve does not quantify the relative amounts of light at each wavelength reflected by a specimen unless it is illuminated by an equal energy source, a theoretical possibility. The next stage in color measurement is, therefore, to determine those relative amounts when the specimen is illuminated by a real source. In 1931 the CIE defined three such sources, Illuminant A, representing the light from a tungsten filament lamp, and Illuminants B and C, representing daylight at a color temperature of ca. 4 900 and 6 800 K respectively. Illuminant A is still valid, Illuminant B rapidly fell into disuse, and Illuminant C was supplemented in 1963 by Illuminant D65, which (unlike C) has the correct amount of ultraviolet radiation.

Formulas and tables for calculating the SPD of daylight at any color temperature between 4000 and 25 000 K were also published, and any other SPD can be used in the calculation, e.g., that of a fluorescent tube, provided that the specimen is not fluorescent. If it is, the only valid calculation is that using the SPD of the light irradiating the specimen during measurement. Therefore, the next stage in color measurement is to multiply the reflectance factor (on a 0 – 1 scale) at each wavelength by the relative amount of light of this wavelength in the illuminant:

$$R(\lambda) \times S(\lambda)$$

Each of these products is then multiplied by the color-matching functions of the standard observer.

The Standard Observer. Most colors can be matched perfectly by mixing red, green, and blue lights. If these are defined, e.g., by wavelength and power, a given observer always requires the same amounts of red, green, and blue lights to match a given color irrespective of its spectral composition. Therefore, these amounts quantify perceived color and are known as tristimulus values *R, G,* and *B*. MAXWELL deduced that if the amounts of *R, G,* and *B* required to match monochromatic light throughout the visible spectrum were determined, these values would enable the tristimulus value of any stimulus to be calculated if the SPD of the stimulus were known. These amounts are known as color-matching functions, and those obtained by GUILD [87] and WRIGHT [88] were adopted by the CIE in 1931 to define the standard observer.

Imaginary Primaries. HELMHOLTZ and MAXWELL had observed that it was impossi-

ble to select red, green, and blue lights that, by additive mixing, could match all monochromatic lights:

$$Q \not\equiv R+G+B$$

where $\equiv$ indicates perfect color matching. However, MAXWELL discovered that a color-matching equation could be set up with any monochromatic light, provided that one of the additive primaries *R, G,* or *B* could be added to *Q*; i.e., for any wavelength $Q(\lambda)$, one of the following color-matching equations could be set up:

$$Q(\lambda)+R \equiv B+G$$
$$Q(\lambda)+G \equiv R+B$$
$$Q(\lambda)+B \equiv R+G$$

Since any monochromatic stimulus could become part of a color matching equation of this type, this also applies to any polychromatic stimulus. The laws of additive color mixing state that color-matching equations could be treated algebraically, and therefore, every light could be specified in terms of *R*, *G*, and *B,* provided that one could be negative, for example:

$$Q(\lambda) \equiv B+G-R$$

In 1931 the CIE decided that it would be unwise to establish a system of color specification employing negative amounts of one of the primaries, but that these could be eliminated by converting *R, G,* and *B* into imaginary primaries *X, Y,* and *Z.* The CIE, therefore, converted the means of the Guild – Wright data involving 17 observers into the amounts, all positive or zero, of three imaginary primaries required to match monochromatic light at every 5 nm from 400 to 700 nm. These amounts are known as the color-matching functions of the CIE 1931 standard colorimetric observer, represented by $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ [85, pp. 104 – 108].

The color-matching experiments of GUILD and WRIGHT involved a split circular field subtending an angle of 2° at the eye, approximately that of a thumbnail held at arm's length. Since industrial color matching employs larger specimens, the CIE established the CIE 1964 supplementary standard colorimetric observer using a split 10° field. These color-matching functions are designated $\bar{x}_{10}(\lambda)$, $\bar{y}_{10}(\lambda)$, and $\bar{z}_{10}(\lambda)$ and are free of the defects subsequently discovered in the 2° data [89]. Both sets have now been interpolated and extrapolated to cover the range of 360 – 830 nm at 1-nm intervals, to about eight significant figures. Unless assessments of color are made on small areas, e.g., color photographs, the color-matching functions of the 10° observer should always be used.

Tristimulus values are calculated by multiplying the product of the reflectance factor $R(\lambda)$ and the spectral power distribution of the illuminant $S(\lambda)$ by each of the three color-matching functions, ideally at every 5 nm from 380 to 780 nm; however, many modern spectrophotometers use values at every 20 nm from 400 to 700 nm. The individual values involving the three functions are then summed and multiplied by a normalizing factor *k* to give the *XYZ* tristimulus values:

$$X = k \sum_{380}^{780} R(\lambda)\, S(\lambda)\, \bar{x}(\lambda)$$
$$Y = k \sum_{380}^{780} R(\lambda)\, S(\lambda)\, \bar{y}(\lambda)$$
$$Z = k \sum_{380}^{780} R(\lambda)\, S(\lambda)\, \bar{z}(\lambda)$$

where

$$k = 100 \left[\sum_{380}^{780} S(\lambda)\, \bar{y}(\lambda) \right]^{-1}$$

The values X_{10}, Y_{10}, and Z_{10} are calculated similarly from the color-matching functions of the 10° observer.

The constant *k* results in the perfect reflecting diffuser (the CIE standard of reflectance since 1969) having a *Y* value of 100.00 under every illuminant. Every modern spectrophotometer has a built-in microprocessor that performs these calculations, and many display tristimulus values for several illuminants by using both the 2° and 10° color-matching functions.

Tristimulus Colorimeters. The first spectrophotometers were expensive and slow and required highly skilled operators. The need for a simpler instrument was met by the tristimulus colorimeter, designed to respond to spectral distributions of light like the human eye. This

was achieved by making the photodetector response spectrally equivalent to the CIE standard observer color-matching functions. For this purpose three or four filters are used [90].

The first commercial colorimeter was developed in 1952 at the National Bureau of Standards (NBS) in Washington, D.C. [90]. Although its accuracy left much to be desired, it provided rapid measurements at low cost. Spectrophotometers are just as fast and easy to use and are able to deal with metamerism, whereas the colorimeters can only duplicate a single observer – illuminant combination.

3.3. Chromaticity Diagram

There are three independent variables of perceived color; in the case of surface colors, they are usually termed lightness, hue, and saturation. Only one of these, lightness, is directly related to a single tristimulus value, the *Y* value; interpretation of the other two variables is facilitated by determining the ratio of each tristimulus value to their sum. These ratios are termed chromaticity coordinates, given by

$$x = \frac{X}{X+Y+Z}$$
$$y = \frac{Y}{X+Y+Z}$$
$$z = \frac{Z}{X+Y+Z}$$

As $x+y+z=1$, only two chromaticity coordinates are required to specify the saturation and hue of any color. Any two could be used, but *x* and *y* are always chosen. The spectrum locus and the purple line representing all the colors obtained by mixing the ends of the spectrum are shown in Figure 13. This continuous line is the boundary of all real colors; the *X, Y,* and *Z* lights, being imaginary, lie outside at the following positions:

$$X \text{ at } x=1, y=0$$
$$Y \text{ at } x=0, y=1$$
$$Z \text{ at } x=0, y=0$$

The position of the two most important illuminants, D65 (daylight) and A (tungsten light) are shown, as well as the positions of two surface colors *P* and *Q*. The hue of *P* can be quantified by drawing a straight line through the positions of D65 and *P* and extrapolating it until it cuts the spectrum locus at λ_d (*P*). The wavelength corresponding to this point is the dominant wavelength of *P* and this is defined by the CIE as the "wavelength of the monochromatic light stimulus that, when additively mixed in suitable proportions with the specified achromatic light stimulus, matches the color stimulus considered."

In the case of surface color *Q,* the line must be extrapolated in the opposite direction to cut the spectrum locus at λ_c (*Q*). The wavelength corresponding to this point is the complementary wavelength of *Q,* which means that when light of this wavelength is added in the correct proportions to light whose chromaticity coordinates are the same as *Q,* the mixture matches the specified achromatic stimulus, usually D65.

Saturation can be quantified by determining the position of the specimen on the line drawn from D65 through the position of the specimen to the boundary, i.e., the spectrum locus in the case of *P* and the purple line in the case of *Q*. A specimen that lies halfway along this line has an excitation purity p_e of 0.5. Saturation can also be quantified by multiplying the excitation purity by y_d/y, where y_d is the *y* chromaticity coordinate of the monochromatic light stimulus and *y* is that of the specimen. This measure of saturation is termed colorimetric purity.

None of these measures of hue and saturation, however, became widely used, which is fortunate because they, together with the *Y* value as a measure of lightness, are unreliable. Specimens that have the same perceived hue but with variation in purity rarely have the same dominant or complementary wavelength. Neither of the two measures of purity is a reliable measure of the perceived variable known as saturation. The value of a grey, which is perceptually midway between black ($Y \approx$ ca. 0) and white ($Y \approx 100$) has a *Y* value of 20 instead of ca. 50. This shows that the *XYZ* space is nonuniform, a fact that was recognized in the mid-1930 s, and more effort has been expended in the search for a uniform color space since that time than that required to develop the CIE system. The principal incentive for this effort, which is still being pursued, is that the distance between the posi-

Figure 13. The CIE 1931 *xy* chromaticity diagram
For explanation of abbreviations, see text

tions of two specimens in such a space would be proportional to their perceived color difference. Such distances are given the symbol ΔE (E is derived from the German *Empfindung* for sensation). Formulas for calculating ΔE are known as color-difference equations, of which more than 20 have been devised since 1935. With most of these, the *XYZ* tristimulus values of standard and batch are first converted into the coordinates of a more uniform color space. The most uniform color spaces devised so far are the CIE 1976 ($L*u*v*$) color space known as CIELUV and the CIE 1976 ($L*a*b*$) color space known as CIELAB.

The CIELUV is primarily intended for additive mixtures of lights; the associated $u'v'$ diagram, a linear transformation of the *xy* chromaticity diagram, possesses the essential attribute that mixtures of two lights are plotted along the straight line joining their positions in the $u'v'$ diagram. The CIELAB, on the other hand, is unsuitable for lights, as the associated $a*b*$ diagram is a nonlinear transformation of the *xy* chromaticity diagram. This is, however, no disadvantage where surface colors are concerned, and CIELAB is used worldwide for this purpose. Consequently, only CIELAB is described in detail here; the equations for calculating CIELUV coordinates are given by CIE [86].

3.4. Conversion of *XYZ* Values into *L*a*b** Coordinates

When the CIE defined the imaginary primaries *X, Y,* and *Z* from the real primaries *R, G,* and *B,* which were monochromatic lights at 700, 546.1, and 435.8 nm, respectively, *X* and *Z* were chosen

to have 0 brightness. This meant that the brightness of any light or the lightness of any colored object would be quantified by the Y tristimulus value alone. The Y values of a series of grey specimens equally spaced perceptually from black to white, however, lie not on a straight line, but on a curve, the grey midway between black and white having a Y value of ca. 20 instead of ca. 50.

The first step in converting XYZ space into a uniform color space is, therefore, to convert the Y values into other values that are linear with respect to perceived lightness. In the CIELAB (and CIELUV) uniform color spaces, these values are designated $L*$ and are given by

$$L^* = 116\,(Y/Y_n)^{1/3} - 16$$
$$\text{if } Y/Y_n > 0.008856 \text{ and}$$
$$L^* = 903.3\,(Y/Y_n)$$
$$\text{if } Y/Y_n \leq 0.008856$$

where Y_n is the Y value of the perfect reflecting diffuser, which is always 100.000.

For a perfect black $L* = 0.00$, for the perfect reflecting diffuser $L* = 100.00$, a grey midway between black and white has an $L*$ value of ca. 50. Similar functions are applied to X and Z, and the CIELAB $a*b*$ coordinates are given by

$$a^* = 500\,[f\,(X/X_n) - f\,(Y/Y_n)]$$
$$b^* = 200\,[f\,(Y/Y_n) - \mathrm{f}\,(Z/Z_n)]$$

where

$$f\,(X/X_n) = (X/X_n)^{1/3} \text{ if } X/X_n > 0.008856 \text{ but}$$
$$f\,(X/X_n) = 7.787\,(X/X_n) + 16/116$$
$$\text{if } X/X_n \leq 0.008856$$
$$f\,(Y/Y_n) = (Y/Y_n)^{1/3} \text{ if } Y/Y_n > 0.008856 \text{ but}$$
$$f\,(Y/Y_n) = 7.787\,(Y/Y_n) + 16/116$$
$$\text{if } Y/Y_n \leq 0.008856$$
$$f\,(Z/Z_n) = (Z/Z_n)^{1/3} \text{ if } Z/Z_n > 0.008856 \text{ but}$$
$$f\,(Z/Z_n) = 7.787\,(Z/Z_n) + 16/116$$
$$\text{if } Z/Z_n \leq 0.008856$$

The values X_n, Y_n, and Z_n are the tristimulus values of the perfect reflecting diffuser (which are the same as those of the illuminant), the appropriate values being

Illuminant D65/10°	$X_n = 94.8$	$Y_n = 100.0$	$Z_n = 107.3$
Illuminant D65/2°	$X_n = 95.0$	$Y_n = 100.0$	$Z_n = 108.9$
Illuminant C/10°	$X_n = 97.3$	$Y_n = 100.0$	$Z_n = 116.1$
Illuminant C/2°	$X_n = 98.1$	$Y_n = 100.0$	$Z_n = 118.2$

Color differences in CIELAB unis are then given by

$$\Delta E = \left[(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2\right]^{0.5}$$

The CIELAB color space, one of the most uniform devised thus far, has another valuable characteristic: all colors are arranged around a central vertical axis, the $L*$ axis. This is the inherently logical visual color-order system that has been discovered, first in the 17th century, and then in this century by Ostwald and Munsell. If the Cartesian coordinates $L*$, $a*$, and $b*$ are converted into cylindrical coordinates, these quantify the three variables of a perceived color : lightness, saturation, and hue.

Saturation is the variable by which a surface color differs from the grey of the same lightness and is quantified by the distance from the achromatic axis. This is given by

$$\left[(a^*)^2 + (b^*)^2\right]^{0.5}$$

and is termed chroma (symbol $C*$), which is the term coined by Munsell. The term saturation should not be used for this variable because it has been defined by the CIE in such a way that it cannot be quantified by CIELAB coordinates and is of little value for object colors. Hue is quantified by the angle that the chroma radius, passing through the position of the color, makes with the positive $a*$ axis; it is given by

$$h = \arctan\,(b^*/a^*)$$

expressed on a scale from 0 to 360°. The relationship between these CIELAB coordinates is shown in Figure 14.

The CIELAB $L*$, $C*$, and h coordinates provide a numerical identification of any color that, unlike XYZ or $xy\,Y$ coordinates, could be understood by artists and designers. Therefore, it has been recommended that all collections of physical specimens, so-called color atlases, should include these coordinates [91].

Figure 14. CIELAB color space

3.5. Calculation of Color Differences

The $L*$, $a*$, and $b*$ values of any color can be regarded as coordinates in a three-dimensional Euclidean space; two colors that are not a perfect match to the 2° or 10° observer under a specified illuminant are not located at the same point in $L*a*b*$ space, and as the match is worse the greater is the separation. This distance is easily calculated by applying the Pythagorean theorem in three dimensions:

$$\Delta E = \left[(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2\right]^{0.5}$$

where

$$\Delta L^* = L^*_{\text{batch}} - L^*_{\text{standard}}$$
$$\Delta a^* = a^*_{\text{batch}} - a^*_{\text{standard}}$$
$$\Delta b^* = b^*_{\text{batch}} - b^*_{\text{standard}}$$

and ΔE is the color difference in CIELAB units. The value $L*$ quantifies the lightness difference: a batch is lighter than standard if $\Delta L*$ is positive and darker if it is negative. Differences in the other two variables of perceived color, chroma and hue, are calculated as follows:

$$C^* = \left[(a^*)^2 + (b^*)^2\right]^{0.5}$$
$$\Delta C^* = C^*_{\text{batch}} - C^*_{\text{standard}}$$

A batch is stronger than standard if $\Delta C*$ is positive and weaker if it is negative. The hue difference, Δh, is given by

$$\Delta h = \left[(\Delta E)^2 - (\Delta L^*)^2 - (\Delta C^*)^2\right]^{0.5}$$

This can be qualified by the terms redder, yellower, greener, or bluer by reference to the $a*b*$ diagram [85, p. 156]. Although CIELAB was found to be the most reliable color difference formula devised up to its inception in 1973, it was not sufficiently reliable to permit decisions on color matching to be made with reference to a value of ΔE that depended only on the closeness of match required. Although an average of 17 % of wrong decisions were made by professional colorists. [92], instrumental decisions based on the optimum value of ΔE were higher. To overcome this defect, visual pass/fail decisions made by professional colorists on many batches dyed to match standards of hundreds of different colors were obtained. This permitted specifications to be made around any point in CIELAB color space of the ellipsoid in such a way that every batch lying on the ellipsoid surface would have the same acceptability rating. The ellipsoids were defined by three semiaxes oriented in the orthogonal directions corresponding to changes in lightness, chroma, and hue, the overall scale being such that batches lying on the ellipsoid surface would exhibit a color difference from the standard of 1 JPC79 unit. Color differences in these units are given by the position of a batch in relation to the point on the ellipsoid surface where the line from the standard location passing through the batch location cuts this surface [93].

This formula was subsequently improved by the Colour Measurement Committee of the Society of Dyers and Colourists [94] and is known as CMC ($l:c$). When $l = c = 1$, the formula quantifies the perceptibility of any small color difference, a value of 1 being about 3 times larger than a barely perceptible difference. Equally perceptible color differences are however, not always equally acceptable as industrial color matches; in particular, differences in lightness are more likely to be acceptable than equally perceptible differences in hue. To allow for this, l and c are tolerances for lightness and chroma differences relative to hue differences, and $l = 2$, $c = 1$ have been found to be the best values for textiles.

Color differences in CMC ($l:c$) units are obtained from the $L*$, $C*$, and h values of standard and $\Delta L*$, $\Delta C*$, and ΔH by using the formula

$$S_L = \frac{0.040975L^*}{1 + 0.01765L^*}$$

unless $L^* < 16$ when $S_L = 0.511$

$$S_c = \frac{0.0638C^*}{1 + 0.0131C^*} + 0.638$$

$$S_h = (fT + 1 - f)\, S_C$$

where $f = \left[\frac{(C^*)^4}{(C^*)^4 + 1900}\right]^{0.5}$

and $T = 0.36 + 0.4\cos(h + 35)$

unless h is between 164 and 34° when

$$T = 0.56 + 0.2\cos(h + 168)$$

Color differences in CMC ($l:c$) units are then given by

$$\Delta E = \left[\left(\frac{\Delta L^*}{S_L}\right)^2 + \left(\frac{\Delta C^*}{S_C}\right)^2 + \left(\frac{\Delta H}{S_H}\right)^2\right]^{0.5}$$

In addition, two formulas M & S83A and Datacolor, have been developed by optimizing the constants against masses of visual data. The former is widely used throughout the world, but since neither has been published and the use of each is confined to the instruments of a single manufacturer, they are not considered here further.

3.6. Colorant Formulation

When increasing amounts of a dye are applied to a substrate, the shape of the reflectance curve changes in a systematic but complex manner, as shown in Figure 15 for red, yellow, and blue dyes. Similarly shaped curves are also obtained when paints are compounded with increasing ratios of chromatic to white pigment. At every wavelength a simple function of reflectance varies approximately linearly with the concentration of chromatic colorant. This function is additive when more than one chromatic colorant is present. It quantifies the coefficient of absorption K divided by the coefficient of scatter S [95], [96]:

$$K/S = (1 - r)^2 / 2r$$

If the *K/S* value for a known concentration of each dye is known, the reflectance curve of any colorant mixture can be predicted from the concentration of each component, but this is of no practical value. The converse procedure, however, is colorant formulation: the reflectance curve of the target shade is measured, the *K/S* values at every 20 nm from 400 to 700 nm are calculated, and the amounts of each colorant are varied until the mixture yields these values. This can only be done effectively by computer. The first was an analogue computer introduced in 1958 in which the calculations were facilitated because all of the scatter was caused by the substrate and because a single constant for *K/S* could be used [97]. This method was successful only for pastel shade paints, because in paints of higher chroma the scattering caused by the chromatic pigment is significant. This necessitated the use of separate constants for K and S, and this could only be carried out on a digital computer.

The first program for a digital computer was devised in 1961 [98]. For textile dyeing the single-constant method was used and in 1964, a two-constant program was written for the same computer for paint formulation [99].

In addition to formulating a mixture with the same reflectance curve as the target shade, a color-matching computer also predicts mixtures yielding the same tristimulus values under D65. Such matches are, of course, metameric, but this is not serious if the degree of mismatch under any conventional illuminant is acceptable. This is indicated by the computer calculating metameric indexes, which are the color differences under every relevant illuminant.

A modern match-prediction system prints out every combination with a maximum metameric index below a preselected value together with the colorant cost, enabling the colorist to make the best choice. The mathematics of computer colorant formulation is extremely complex [85, pp. 172 – 186], [100–102].

4. Chemical Analysis and Tests

Industrial analysis of dyes aims at (1) homogeneity testing, (2) separation of mixtures, (3)

Figure 15. Reflectance curves of cotton dyes with increasing amounts of a red dye (A), a yellow dye (B), and a blue dye (C)

classification, (4) identification, and (5) quantitative determination [103].

Commercial dyes number several thousands and there is no universally valid scheme of analysis. A conclusion may be drawn about the type of dye if additives such as sodium sulfide, sodium dithionite (hydrosulfite) or substrates (alumina, barium sulfate, titanium dioxide, etc.) are found. In the dyeing of cellulose acetate, polyester, and polyamide fibers and plastics, as well as for spin dyeing, pigment printing, and other purposes, such additives as emulsifiers (→ Emulsions), dispersing agents, plasticizers, and others may be present. Water-soluble liquid preparations may contain glycols, glycol ethers, formic acid, acetic acid, or xylene, whereas liquid grades of oil-soluble dyes often contain mixtures of high-boiling aromatic compounds. On the fiber, dyes are sometimes associated with chromates, finishing agents, textile softeners, mordants, and aminoplasts, all of which must be separated for analysis.

4.1. Investigation of Individual Dyes

4.1.1. Testing for Homogeneity and Separation of Mixtures

The quickest and simplest test for dye homogeneity is the *blowing test,* in which a small sample of powdered dye on the tip of a spatula is blown against a moist filter paper, which may then be heated. In case of a dye mixture prepared by dry mixing, the particles on the paper dissolve with their characteristic color and the different dyes can be distinguished. The paper can also be moistened with ethanol, acetone, dimethylformamide, hydrochloric acid, or sodium hydroxide. Moistening first with acid and then with base often produces a color change. The dye can also be blown onto concentrated sulfuric acid in a porcelain dish to give characteristic colors. The blowing method fails when the dye mixture has been made by wet blending (of dye solutions) and with paste-type and liquid dyes.

Dye mixtures can often be separated by *fractional dissolution.* Thus, disperse dyes can be dissolved with acetone or ethyl acetate out of mixtures of acid dyes or substantive and vat dyes. Acid dyes can be separated from substantive dyes on the basis of their different solubility in ethanol, acetone, acetic acid, and other solvents. With acid solvents, the substantive or direct dye is sometimes left behind as water-insoluble free acid or salt. Basic dyes on the other hand, can be extracted from aqueous solutions by ether.

Water-soluble dyes can be separated by *solvent partition* [104]. Water is used as one phase; amyl alcohol, possibly mixed with a second solvent, is the other. In this way, dyes can be divided into eleven groups.

Other methods include *reduction and oxidation.* For example, in a mixture of water-soluble Quinoline Yellow and an azo dye, the azo dye can be reduced with ammonia and zinc dust, whereas the Quinoline Yellow remains unaltered. In a mixture of Copper Phthalocyanine Blue and Green, the blue component is oxidized by boiling nitric acid but the green remains unchanged.

Often it is possible to separate a mixture by *fractional dyeing,* first for a short time at low temperature with a small amount of material and then with fresh material at higher temperature. Repeated dyeing at various pH values may also achieve the objective. In the case of mixtures for dyeing fiber blends, fractional dyeing is often possible on the individual types of fibers.

Chromatographic methods, such as column chromatography, paper chromatography, thin-layer chromatography (in its various forms), and high-performance liquid chromatography, particularly in the reverse-phase mode, have proved excellent both in testing for dye homogeneity and in analytical separation and determination of mixtures (see Chap. 5). These methods can also be used on a preparative scale for the isolation of components of mixtures.

Paper electrophoresis is useful for indicating the electrical charge on a dye molecule or complex, particularly when the charge on the cation (Co or Cr) is modified by one or more sulfonic acid groups in the aromatic rings [106].

Dyes can be separated from foods by shaking them with polyamide powder in acid solution; the water-soluble dyes are adsorbed, but the water-soluble foods are not and are washed off. Methanol – ammonia serves for desorption of the dyes.

4.1.2. Classification

For a preliminary classification, behavior in water, dilute sodium hydroxide, and alkaline sodium dithionite is investigated. Table 6 lists the conditions of the dyeing test.

Water-soluble Dyes. Most water-soluble dyes dissolve immediately without color change. They can be classified by a few tests of their behavior toward wool, cotton, tannin-treated cotton, and cellulose acetate (Table 6).

Basic dyes give positive results on tannin-treated cotton and cellulose acetate, but not on wool (with some exceptions) or cotton.

Sodium hydroxide usually changes or decolorizes solutions of basic dyes. The dye can then be extracted with ether and back-extracted into dilute acetic acid. Basic chrome dyes are not absorbed in ether. Many basic dyes are not resistant to alkali. Some basic dyes, such as Victoria Blue grades, dye wool. A solution of 5 % tannin and 5 % sodium acetate precipitates basic dyes, and also dyes that contain sulfonic acid groups.

Table 6. Dyeing tests

Dye solution	Material (50 – 100 mg)	Procedure
5 cm^3 dye solution ∗ + 1 cm^3 15 % acetic acid	Wool and tannin-treated cotton	Boiling for a few minutes
5 cm^3 dye solution ∗ + 1 cm^3 5 % Na_2SO_4 solution	Cotton	Boiling for a few minutes, followed by a brief rinse with warm water
5 cm^3 dye solution ∗ + 1 cm^3 2.5 % soap solution	Cellulose acetate	Dyeing at 70 °C

∗ Containing 1 – 5 mg dye per 5 cm^3

Basic dyes are also precipitated with perchloric acid.

Acid dyes, *mordant dyes*, *acid metal-complex dyes*, and *leuco esters of vat dyes* dye wool, but not cotton or cellulose acetate; tannin-treated cotton is slightly dyed.

The acid metal-complex dyes are easily identified by testing an ashed sample for Cr, Co, Fe, Ni, or Cu. The leuco esters of vat dyes are detected by oxidation with sodium nitrite in sulfuric acid to the vat dyes, which can again be vatted in alkaline solution with hydrosulfite. If the tests for these two groups are negative, the wool is dyed from acid solution, followed by chroming. If there is a change of hue compared with the acid dyeing and if the washfastness improves, a chrome-developed or mordant dye is indicated; otherwise, it is an acid dye. The washing test is essential, because with many acid dyes, the hue is altered by oxidation, but washfastness is not improved.

Substantive or *direct dyes*, *diazotized dyes*, *developed dyes*, *aftertreated dyes,* and *reactive dyes* give positive results on cotton. Wool may be dyed partially; tannin-treated cotton may be dyed slightly or merely soiled; cellulose acetate is soiled.

To distinguish between an ordinary direct dye and a diazotized, developed, or coppered dye, substantive dyeing is followed by the appropriate posttreatment, and the untreated dyeing is compared with the posttreated dyeings with respect to fastness properties. If the posttreatment has improved fastness, an ordinary direct dye is probably not present.

Disperse dyes give positive results on cellulose acetate, but not on wool or cotton.

Disperse dyes can usually be extracted with ethyl acetate and are often soluble in acetone. If wool is stained in addition to cellulose acetate, dye mixtures for wool – polyester blends may be present, which in addition to disperse dyes usually contain 1 : 2 metal-complex dyes without sulfonic acid groups.

Sulfur and *vat dyes* dissolve slowly in water, often accompanied by a color change. The dyes giving positive results on wool contain reducing agents and are partly in the leuco form, in which they cannot be investigated. They must first be oxidized by blowing air into the vat solution. Alternatively they are separated from the reducing agent by dyeing and then investigated on the fiber. For this purpose, wool and cotton are dyed in the same vat solution at 60 °C.

For further differentiation, the cotton dyeing is tested for sulfur dyes with tin(II) chloride, hydrochloric acid, and lead acetate paper. Sulfur dyes and sulfur-vat dyes of the Hydron Blue type can be distinguished from vat dyes by treatment with 10 % sodium sulfide solution at 95 °C. This solution does not reduce vat dyes.

Dyes Insoluble in Water. The *alkali-soluble mordant dyes* give sparingly soluble color lakes in aqueous dispersion with solutions of metal salts when heated to ca. 70 °C, with simultaneous deepening of hue. Tests are made with chromium (III) sulfate, aluminum sulfate, and copper sulfate, or with iron(III) chloride. For confirmation, pre-chromed wool is dyed in an acetate bath, followed by fastness tests to washing and milling.

Color lakes of acid dyes leave metals, such as Ba, Sr, Ca, and Mn, in the ash. The dye is dissolved in sodium hydroxide solution and investigated in the same way as water-soluble dyes.

Alcohol-soluble dyes are usually anionic and often are salts of cyclohexylamine, dicyclohexylamine, 2-ethylhexylpropylamine, or di-o-tolylguanidine.

Color lakes from basic dyes are boiled with 10 % sodium hydroxide. The liberated dye bases are extracted into ether and back-extracted into dilute acetic acid as colored salts.

Dyes dissolving in sodium hydroxide and dithionite with a change in color, can be divided according to solubility: the *organic pigments* (azo or nitro dyes) are sparingly soluble or insoluble in ethanol, oils, and waxes; in this they differ from the *oil- and fat-soluble dyes* (Sudan dyes and Ceres dyes). The *alcohol- and ester-soluble dyes* in this group (Zapon-fast, Neozapon, Irisol-fast) are sometimes metal complexes, giving ash that contains such metals as Ni, Co, Fe, Mn, Cr, or Al.

Water-soluble vattable dyes, used for wool and cotton, are subdivided into *sulfur dyes* and *sulfur vat dyes* (e.g., Hydron Blue). These give a colored vat and can also be converted to the leuco form with sodium sulfide. Sulfur dyes are used with common salt, especially in the case of deep hues, and the Hydron Blue group is used with hydrosulfite.

If cotton dyed with dyes in this group, or the dye itself, is heated first with dilute hydrochloric acid and then with a solution of tin(II) chloride, it is possible to detect hydrogen sulfide with lead acetate paper.

Anthraquinone vat dyes in most cases give deep-colored vats, often differing considerably from the color of the dye.

Like the sulfur dyes, leuco *indigoid dyes* are only faintly colored; they do not vat with sodium sulfide, but require sodium hydrosulfite and sodium hydroxide.

4.1.3. Identification

A homogeneous dye can be identified by comparison with a known dye [106]. Identification requires comprehensive tables of reactions of dyes, dyeings, and prints [107]. Final identification requires a comparison with an authentic specimen [108–117].

An identification scheme for organic pigments and color lakes, mainly of the azo series, has been based on the crystal forms that precipitate from concentrated sulfuric acid [118].

4.1.4. Quantitative Determination

Organic dyes can be determined by a dyeing or comparison by chemical or spectroscopic methods. With dye mixtures, dyeing tests are preferred to chemical-analytical methods.

Dyeing Strength. In the determination of dyeing strength, the same conditions and the same material are used as for the standard to obtain two dyeings as nearly equal in depth as possible. If several types of fibers are to be dyed with the same dye, the color strength on each fiber must be determined. For dyes with low affinity (disperse dyes and leuco esters of vat dyes), the strength is determined at various depths of color, if a different dye is used for comparison; the result is affected by the affinity of the dye.

Elemental Analysis. Chemical methods for quantitative determination of a dye can be used if its molecular mass is known. Elemental analysis can be employed when the dye contains an element that is absent in other components of the commercial dye.

Reduction. Reduction methods can be used with most dyes except the quinophthalones, oxidation dyes, and thiazol dyes. Reduction is usually effected with titanium(III) chloride [*7705-07-9*] or titanium(III) sulfate [*10343-61-0*] [119–121]. Many azo dyes, especially if acid soluble, can be titrated with titanium(III) chloride directly; sodium tartrate, oxalate, or fluoride is often added [122]. Sometimes excess reducing agent is used and back-titrated with iron(III) salt [123]. If the end point is obscured by color, the solution can be lightened by adding ethanol or acetic acid; potentiometric titration is also used [124]. The following reductions take place:

$$R{-}N{=}NR' + 4\,Ti^{3+} + 4\,H^{+} \longrightarrow RNH_2 + R'NH_2 + 4\,Ti^{4+}$$

$$RNO_2 + 6\,Ti^{3+} + 6\,H^{+} \longrightarrow RNH_2 + 6\,Ti^{4+} + 2\,H_2O$$

Triarylmethane, azine, oxazine, and thiazine dyes are determined similarly, consuming 2 equivalents of titanium(III) for 1 mol of dye. Indigo is sulfonated before the determination.

Mixtures of dyes can be titrated successively with $TiCl_3$ in 30 % acetic acid [125]. To avoid nuclear chlorination, $Ti_2(SO_3)_4$ has

Table 7. Behavior of dyes on cellulose fibers

Dye class	Boiling with ∗ (a)	(b)	(c)	(d)	(e)	Comments
Direct dyes without treatment	+	–	–	+	(+)	wool. Tests should be performed to check if the color of the solution of both fibers is identical in concentrated H_2SO_4. If not, a mixture of acid dyes may be present.
Reactive dyes	(+)	–	–	(+)	(+)	Only small amounts of unreacted or hydrolyzed dye extracted.
Diazo dyes	–	–	(+)	–	+	
Direct dyes treated with Cu, Cr, or CH_2O	(+)	–	–	(+)	+	Test dyeing for CH_2O or ash for presence of Cu and Cr.
Insoluble azo dyes	–	(+)	+	–	–	All are destroyed by sodium hypochloride precipitated on the fiber rite and pyridine; yellow dyes are more resistant. Red dyes are resistant against sodium hypochlorite and hydrochloric acid.
Vat dyes	–	(+)	(+)	–	–	Many vat dyes are insoluble in all five solvents. Transform into vat and reoxidize on fiber.
Sulfur dyes	–	–	–	–	–	
Spin-dyeing pigments	–	–	(+)	–	–	Easily recognized on microscopic examination by pigmentation of fiber
Oxidation base dyes (aniline black)	–	–	–	–	–	
Mordant dyes	–	+	+	–	–	Give typical color changes with sodium hydroxide; some fluoresce. Basic dyes do not dissolve in ether.
Basic dyes	–	+	+	–	–	
Acid dyes	+	–	–	(+)	(+)	Used only as printing dyes on viscose rayon. Extracts dye wool (see Table 6).

∗ Abbreviations: a) water; b) alcohol; c) glacial acetic acid; d) 20 % aqueous ammonia; e) aqueous ammonia – alcohol solution; + dye is extracted; (+) dye is extracted in some instances or is partially extracted; – dye is not extracted.

Dye class	Boiling with ∗ (a)	(b)	(c)	(d)	Comments
Acid dyes ∗∗	(+)	–	–	+	
Chrome and mordant dyes	–	–	(+)	(+)	Ash of dyeings contains metal.
Acid complexed dyes	–	–	–	(+)	Ash of dyeings contains metal, which is found in redyeings with the stripped dye.
Direct dyes	(+)	–	–	(+)	
Basic dyes	(+)	+	+	(+)	
Vat dyes for wool	–	–	(+)	–	Strip with ammonia or with aqueous piperidine and dithionite.

∗ Abbreviations: (a) water; (b) alcohol; (c) glacial acetic acid; (d) 20 % aqueous ammonia; + dye is extracted; (+) dye is extracted in some instances or partially extracted; – dye is not extracted.
∗∗ Some are soluble in all solvents.

been recommended [126]. Vanadium(II) sulfate [*36907-42-3*] is also suitable for the determination of azo dyes [127]. Tin(II) chloride and sodium dithionite [*7775-14-6*] are now less important for this purpose and for the cleavage of azo dyes [128], [129].

Oxidation. Azo dyes (except insoluble ones without hydroxyl groups) and water-soluble triphenylmethane and anthraquinone dyes can be determined quantitatively by oxidation with chromic acid [*1333-82-0*]. The nitrogen present is liberated as the element and determined volumetrically [130], [131]. Various triphenylmethane dyes can be determined oxidimetrically with cerium(IV) sulfate [*17106-39-7*] [132],

[133]. This method is also suitable for the determination of benzidine derivatives [134].

Precipitation. Precipitation methods are also employed for quantitative determination. Anionic dyes are precipitated by cation-active compounds, in particular cetyltrimethylammonium bromide [135], [136]. A standardized solution of cetyltrimethylammonium bromide [*57-09-0*] in chloroform is used for titrimetric determination. Certain basic dyes can be determined with such anion-active compounds as alkyl sulfonates and sulfates. Basic dyes can also be precipitated from acid solution with phosphotungstic [*12067-99-1*] or silicotungstic acid [*12027-38-2*] [137].

4.1.5. Determination of Structure

In determining the structure of a dye, it is first necessary to identify the chemical class to which the dye belongs. Depending on its solubility, a dye can be dissolved in water, alcohol, or dimethylformamide for reduction, and the solubility can be increased by adding sodium hydroxide [107].

The behavior of *water-soluble dyes* toward reducing agents is determined by heating the dye in an aqueous solution with sodium hydroxide and dithionite.

Hue is not changed: quinophthalones, acridines, thiazoles, auramine, and azo dyes.

Hue changes and the dye is reconstituted on oxidation or another colored product is formed: anthraquinones, phthalocyanines, and azo dyes.

Dye fades and original shade returns upon exposure to oxidizing agents (air or persulfate): azines, oxazines, dioxazines, thiazines, and triphenylmethane dyes.

Dye fades and original hue does not return upon reoxidation: azo dyes, nitro dyes, and nitroso dyes.

The behavior of *water-insoluble dyes* toward reducing agents is determined by heating the dye in aqueous suspension with sodium hydroxide and dithionite:

Hue does not change: quinophthalones, dioxazine pigments, azo dyes, and phthalocyanines.

Hue changes and hue is reconstituted on re-oxidation: anthraquinones, indigoid dyes, benzo- and naphthoquinones, sulfur dyes, and phthalocyanines.

Dye is destroyed and not reconstituted upon re-oxidation: azo dyes, nitro dyes, and nitroso dyes.

Pyrazolone azo dyes can be recognized by a specific reduction technique. All dyes in this class exhibit red-violet to blue-violet hues during re-oxidation in air, when the reaction solution containing ammonia and zinc dust, with added 1-naphthol, is poured onto filter paper [107].

The color of the solution in sulfuric acid may indicate the chemical nature of the dye:

Nitro dyes	yellow to orange
Xanthene dyes	yellow to red
Triphenylmethane dyes	
basic, acid	yellow, orange, reddish-brown
mordant	red
Oxazine dyes	orange-brown, bordeaux, olive green
Azine dyes	green
Thiazine dyes	green
Dioxazine dyes	blue, green, almost black
Azo dyes	yellow to green
Anthraquinone dyes	yellow to green

It is very difficult to determine the structure of dyes, and there are no methods of general applicability. Elemental analysis can provide valuable information, but this requires a pure diluent-free specimen. The infrared spectrum can yield information on structure, but is probably used most often for comparison with known dyes. Proton and ^{13}C NMR give useful information on the aromatic-to-aliphatic ratio and the aromatic substitution. Field desorption and fast atom bombardment mass spectrometry provide data on molecular mass and structure.

Separation of Water-Soluble Additives. Before analysis, water-soluble dyes must be separated from water-soluble additives and the following methods can be used for this purpose.

1) If the dye is insoluble in acid, as with most substantive dyes, the dye can be precipitated from aqueous solution with hydrochloric acid and washed. After drying, the sodium salt can be obtained and purified by crystallization. Many polysulfonic acids do not separate from acid solution as free acids, but as acid salts. If only the chlorine content is to be

determined, water-soluble dyes can be salted out with sodium sulfate; sodium chloride is used to precipitate dyes for sulfur determination.

2) Pure sodium salts can be obtained by precipitation from aqueous solution with 2-tolylguanidine hydrochloride and by reconversion to the sodium salt by reaction with the calculated quantity of sodium methoxide in methanol solution.
3) If the dye can be precipitated from aqueous solution with sodium acetate, the precipitate is dried and the excess sodium acetate is extracted with absolute alcohol.
4) In the case of basic dyes, suspension agents (sodium sulfate, sodium chloride, dextrin) can be removed by extraction of the dye into ethanol, or it can be precipitated as the perchlorate.
5) Dispersing agents can be removed from disperse dyes by passage through a membrane filter or by dialysis.

Anthraquinone Dyes. For simple anthraquinone dyes (acid, basic, disperse, and mordant dyes) some methods permit systematic degradation (→ Anthraquinone Dyes and Intermediates). However, anthraquinone vat dyes require special techniques.

Azo Dyes. Azo dyes are usually cleaved into the individual starting amines by reduction, less often by oxidation. Tin(II) chloride [*7772-99-8*] was employed as early as 1888 [138–140]. Other suitable reductants are sodium hydrosulfite [*7775-14-6*], $Na_2S_2O_4$ [141] and titanium(III) chloride [*7705-07-9*]. Cleavage of azo dyes by catalytic hydrogenation appears to have found little application thus far for determination of structure [142], [143].

Polyazo dyes are cleaved similarly. In some cases, especially in the absence of free hydroxyl and amino groups, reduction stops at the hydrazo stage. At that time either the dye is reformed by oxidation or a benzidine or semidine rearrangement takes place in this acid environment. The goal is often achieved by reduction with titanium(III) compounds. Because many dyes contain acylamino, alkyl, or arylsulfonic or urea groups, it is sometimes advisable to hydrolyze before cleavage. With complicated polyazo dyes, cleavage may not yield information on the arrangement of the original structure. Synthesis may be required for a final answer.

Cleavage with Nitric Acid. If nitro groups are present, these are also reduced during reductive cleavage of azo dyes, or if they are in an ortho position to the azo linkage, they may form triazole rings. In this case cleavage with fuming nitric acid [*7697-37-2*] may be preferred for monoazo dyes.

$$R^1-N=N-R^2 \xrightarrow{HNO_3} [R^1-N=N]^+ + R^2-NO_2$$

A negatively substituted nucleus R^1 is obtained as a diazo compound, and a positively substituted nucleus R^2 is obtained as a nitro compound; further nitration of both nuclei is possible [114].

4.2. Investigation of Dyes on the Fiber

The dye class of a dyed article or a print is of great importance for the assessment of fastness, adjustments, processing, and finishing. The fiber analysis of a dyed article permits the exclusion of some dye classes. Identification of individual dyes requires expertise and the availability of an extensive collection of dyes for comparison. Identification of the class is more feasible than identification of an individual dye.

Tables have been available for a long time that give systematic analytical procedures for determining the chemical and dye class of dyes on fibers [144–146]. American methods have been published by the AATCC (American Association of Textile Chemists and Colorists) [147], [148]. Simple schemes are available for rapid determination of dyes on the fiber [117], [149–151]. A systematic scheme based on German experience has been published [152].

4.2.1. General Tests

Cellulose fibers burn evenly to produce a characteristic odor and a soft ash. Wool and silk can also

be recognized by burning (odor of burned horn); these fibers are soluble in boiling 5 % sodium hydroxide. Synthetic fibers can be differentiated by their solubility in solvents

If the warp and weft are different, the threads should be separated mechanically. Printed samples should be cut into areas with the same hue and treated separately. Dyed articles can be submitted to an ash test for metals (chromium, cobalt, copper, nickel, iron, tin, and aluminum) [145].

Treatment with solvents provides important information. The dye may be dissolved from the fiber completely, partly, or not at all (Tables 7 and 8). This method is especially suitable for cellulose and protein fibers [153].

When treated with sodium dithionite and aqueous sodium hydroxide, pyridine, or ammonia, many dyes are removed from the fiber or decomposed. Another reducing agent often used on the fiber is tin(II) chloride. Suitable oxidizing agents are sodium hypochlorite, permanganic acid (potassium permanganate + sulfuric acid), hydrochloric acid, and nitric acid [154].

Fluorescence can sometimes be employed for identification purposes [155]. Some dyes fluoresce on the fiber (e.g., Brilliant Sulfoflavine FF, Auramine O and G, Rhodamine B, G and 6G, Eosin, Sulforhodamine B and G, Fast Acid Pink B, Erio Fast Brilliant Flavine BBL, and Acid Red XG and XB); others fluoresce only in certain solvents or in vat form (Table 9).

Table 9. Fluorescence of dyes

Dye	Solvent	Fluorescence
Yellow dyes of the acridine class	98 % H_2SO_4	green
Indanthren Brilliant Orange GR	vat	red
Indanthren Red GG	98 % H_2SO_4	red
	pyridine	greenish yellow
Indanthren Red 5 GK	ether layer above vat	orange
Sulforhodamine BG ex.	98 % H_2SO_4	green
	pyridine	orange red
Indanthren Brilliand Pink R	benzene	yellow
Indanthren Brilliant Violet RK	pyridine	cyan
Indanthren Brilliant Violet BBK	pyridine	cyan
Indanthren Brilliant Violet 2 R	pyridine	orange red
Indanthren Deep Blue BO	benzene	reddish blue
Indanthren Deep Blue BOA	pyridine	red
Indanthren Marine Blue G	pyridine	reddish violet

4.2.2. Systematic Analysis

Detection of dyes on different fibers is covered in Tables 10, 11, 12; for details, see [152]. The dyed article is first boiled with distilled water to remove surface dyes for direct investigation. This is followed by repeated extraction with ammonia, glacial acetic acid, ether, or other solvents.

4.2.3. Special Tests

Certain methods are specifically applicable to naphthol and reactive dyes.

Naphtol AS Dyes. Combinations with yellow naphthols (Naphtol AS−G, −L3G, −L4G) remain almost unchanged by treatment with sodium hydroxide solution and dithionite, but are attacked by sodium hypochlorite and hydrochloric acid. Reductive cleavage of yellow naphthols is slow and incomplete.

Dyes from red naphthols are very resistant to sodium hypochlorite and hydrochloric acid, but they are bleached by sodium hypochlorite and pyridine. These combinations also resist sodium hydroxide and dithionite in the cold.

Dyes from the Fast Blue bases, Fast Violet bases, and Variamine Blue salts with arylamides of 2-hydroxy-3-naphthoic acid are bleached by sodium hypochlorite and pyridine and are converted to brown hues by sodium hypochlorite and hydrochloric acid. They are, however, resistant to sodium hydroxide and dithionite in the cold.

Color Reactions of Naphtol AS Combinations. With dyes from the same base, the color reactions differ only if the hydroxycarboxylic acid or acetocarboxylic acid forming the basis of the naphthol is different. Thus all red naphthols with the same base give similar color reactions. On the other hand, color reactions differ for combinations from the same base and arylamides of different hydroxycarboxylic acids. These can be distinguished from other naphthols by the yellow-green fluorescence, which is exhibited by solutions of red naphthols after cleavage with dithionite. Thus two groups of combinations are obtained: (1) from red naphthols and (2) from Naphtols AS−LB, AS−SG, AS−SR, AS−GR, AS−BT, AS−S, AS−CB, and yellow naphthols.

Table 10. Identification of dyes on cellulose * [152]

Procedure A: Pyridine is colored: sulfur, oxidation-base, mordant, acid, direct, and basic dyes; followed by test for the presence of sulfur

- Sulfur test positive: sulfur dyes (confirmation: reduction and reoxidation; blue dyeings turn violet when spotted with cold conc. nitric acid)
- Sulfur test negative: oxidation-base, acid, mordant, direct, and basic dyes; followed by testing for black dyeings with alkaline dithionite
  - Black colors turn brown and return to black on exposure to air: oxidation-base dyes; follow-up treatment with cold conc. sulfuric acid and dilution with water
    - Solution turns green: Aniline Black Test for Cr positive; turns black in potassium ferrocyanide test: positive for Fe
    - Color of solution unchanged: Diphenyl Black
  - If no black color develops or if reaction is negative: acid, mordant, direct, or basic dyes; followed by stripping with glacial acetic acid and dyeing of acrylics
    - Acrylics are dyed: basic dyes (confirmation: a) tannin/antimony potassium tartrate mordant, b) Katanol (Cassella) mordant)
    - Acrylics are not dyed: acid, mordant, and direct dyes; subsequent stripping with conc. ammonia or glacial acetic acid and dyeing reaction
      - Wool is colored more deeply: acid and mordant dyes; followed by tests for Cr, Fe, and Al
        - positive: mordant dyes
        - negative: acid dyes
      - Cotton is colored more deeply: direct dyes; followed by tests for Cu, formaldehyde, cationic products
        - positive: direct dyes treated with Cu or Cr salts, CH_2O, or cationic textile additives
        - negative: direct, diazo, or coupling dyes; differentiation should be attempted by comparison tests for fastness

Procedure B: Pyridine is not colored: sulfur, reactive, phthalocyanine, vat, and naphthol dyes; followed by test for sulfur

- Sulfur test positive: sulfur dyes (confirmation: reduction and reoxidation)
- Sulfur test negative: reactive, phthalocyanine, vat, and naphthol dyes; subsequent treatment: boiling with dimethylformamide
  - Test solution not colored: reactive dyes
  - Test solution colored: phthalocyanine, vat, naphthol dyes; subsequent treatment: boiling for 1 min with glacial acetic acid
    - Test solution not colored: phthalocyanine dyes (confirmation: treatment with cold conc. HNO_3 gives violet color; positive for Cu or Ni)
    - Test solution colored: vat and naphthol dyes; subsequent treatment: reduction and reoxidation
      - positive: vat dyes, differentiation between indigo and other blue vat dyes with HNO_3 and $SnCl_2$
      - negative: naphthol dyes (confirmation: fluorescence test; follow instructions for green naphthols)

* The microscopic examination for pigments, spin dyeings, and delustering is followed by treatment with cold pyridine.

Table 11. Paraffin tests for the identification of dyes on animal fibers [152].

- Paraffin colored: vat and naphthol dyes; reduction reoxidation
  - Hue changes and reappears: vat dyes
  - Test solution turns yellow; the test pattern does not change; if it does change, the original hue does not reappear on reoxidation: naphthol dyes
- Paraffin not colored: basic dyes, 1:1 metal complex, 1:2 metal complex, chrome, acid, direct, and fiber-reactive dyes; test for metals:
  - Positive for chromium and cobalt: 1:1 or 1:2 metal-complex or chrome dyes; extract dye with ammonia; acidify solution with hydrochloric acid and extract with ether:
    - Ether is strongly colored: 1:2 metal-complex dyes without sulfo groups
    - Ether is colored only weakly or not at all: 1:1 or 1:2 metal complex dyes with sulfo groups, chrome dyes
  - Negative for chromium and cobalt: basic, acid, direct, and reactive dyes; extraction with cold glacial acetic acid:
    - Glacial acetic acid is colored: basic dyes
    - Glacial acetic acid is not colored: acid, direct, and reactive dyes; extraction with cold pyridine:
      - Pyridine solution not colored: reactive dyes
      - Pyridine solution colored: acid and direct dyes; dyeing test:
        - Wool fiber dyed more strongly: acid dyes
        - Cotton fiber dyed more strongly: direct dyes

Table 12. Identification of dyes on synthetic fibers [152]

- Extract samples A* or B** with ethers
  - Ether layer is colored:
    - disperse, developed disperse, procinyl, naphthol, and vat dyes; fluorescence test on ether layer:
      - Positive: naphthol and developed disperse dyes: boiling in 50% aqueous pyridine
        - Dye precipitates and solution is strongly colored: developed disperse dye
        - Dye does not precipitate or solution is only faintly colored: naphthol dye
      - Negative: on PA: disperse or procinyl dyes on PE: disperse dyes boiling in glacial acetic acid, addition of ether and water:
        - Precipitate white: disperse dye
        - Precipitate colored: procinyl dye
    - disperse, metal complex, and chrome dyes; test for metals:
      - Negative: disperse dyes
      - Positive: metal-complex and chrome dyes; treatment with pyridine and ether:
        - Ether is colored: 1:2 metal-complex dyes without sulfo groups and chrome dyes
        - Ether is not colored: metal-complex dyes with sulfo groups
  - Ether layer is not colored: metal-complex, chrome, basic, acid, and vat dyes; test for metals:
    - Negative: Basic and acid dyes
      - on PA: acid dye
      - on PAN: boiling in glacial acetic acid, dyeing with acrylics
        - Acrylics are colored: basic dye
        - Acrylics are not colored: acid dye

* From polyester (PE) and polyamide (PA) fibers: caprolactam melt = sample A; vat dye test: residue of ether extraction after caprolactam melt is treated with alkaline dithionite, followed by reoxidation; changes in hue indicate presence of vat dyes.

** From polyacrylonitrile (PAN) fibers: stripping with glacial acetic acid = sample B.

With group 1 it is best to determine the base first. Combinations of red naphthols with a number of bases (Garnet GC, GBC, Corinth V, Brown, Blue and Violet) give characteristic color reactions.

With group 2, some conclusions can be drawn from the hue; investigation is simpler because only one or two arylamides of the relevant hydroxycarboxylic acids are on the market.

Naphtol AS combinations can be identified on the fiber by IR spectral comparison. The dye is removed from the fiber with dimethylformamide for the purpose. An NMR spectrum, if obtainable, helps to distinguish between closely related structures.

Reactive Dyes [156], [157]. The dyed sample is boiled with a nonionic surfactant, and tests are then conducted to establish the presence of reactive dyes.

The sample is boiled successively, with intermediate cold water rinses, with glacial acetic acid – ethanol (1 : 1), 1 % aqueous ammonia, dimethylformamide – water (1 : 1), and dimethylformamide. If no bleeding occurs during these treatments, a reactive dye is present. For identification of reactive dyes of the Remazol type (with vinyl sulfone as the reactive group), the sample can be boiled with a white wool thread in a solution containing 1 mL of concentrated sulfuric acid and 2 g of sodium sulfate per liter. Only Remazol dyes do not bleed in this test.

For further identification, the ash can be tested for Cr, Co, Cu, and Ni. For differentiation of blue reactive dyes from the anthraquinone and phthalocyanine series, the sample is treated at room temperature with a solution of 20 g of hydrosulfite and 2.5 g of sodium hydroxide per liter. Phthalocyanine derivatives exhibit blue, and anthraquinone derivatives exhibit brownish blue [158].

Other Special Tests. A simple method has been reported for the investigation of dyes on polyacrylonitrile [159]. Phthalocyanine derivatives can be identified on cellulose and distinguished from other types of dyes [160].

5. Chromatography

Theoretical principles and methods of chromatography are treated elsewhere in this Encyclopedia. In the following, only its special application to dyes is described. Chromatography of dyes is suitable for

1) Testing for purity and homogeneity
2) Separation of mixtures
3) Identification of individual dyes
4) Identification of unreacted intermediates and toxic impurities

The investigation of dyes employs column chromatography (CC), paper chromatography (PC), thin-layer chromatography (TLC), high-performance thin-layer chromatography (HPTLC), and high-performance liquid chromatography (HPLC). *Column chromatography* is suitable for separations on a preparative scale and is often better adapted than paper or thin-layer chromatography for the separation of trace substances. Trace substances in dilute solution can be concentrated by column chromatography and then eluted with a suitable solvent. *Paper chromatography and thin-layer chromatography* are simpler and more reproducible than column chromatography and produce chromatograms that can be stored.

5.1. Column Chromatography [161–165]

Only a few substances are suitable adsorbents for separating dye mixtures. Alumina [*1344-28-1*] and bleaching earths are used with organic media; mixtures of alumina with talc [*14807-96-6*] or with calcium salts are used with aqueous solutions [154, p. 56], [166–168].

Polyamide powder has been used with food and other dyes [169–174]. Gel permeation chromatography (GPC) [175], [176], and chromatography on silica gel [*7631-86-9*] [177], and anionic exchange resins [178] have also been used for food dyes.

Fluorescein and its derivatives [179] and oil-soluble dyes [180] can be separated on silica gel, and aminoanthraquinones can be separated on alumina [181], [182]. Vat dyes can be separated by high-temperature chromatography on alumina [183], and thioindigo derivatives can be separated on silica gel [184].

An alternative form of column chromatography employs polypropylene columns packed with silica-based sorbents [185].

5.2. Paper Chromatography [154, p. 52], [186–188]

Capillary analysis, a precursor of paper chromatography, has long been practiced in color laboratories. A filter paper with good absorption properties is dipped into a hot dye solution. The individual dyes rise at different rates; the components with the fastest rate of migration can be detected at the upper edge of the dye front after a short time (frontal analysis). The dye solution is supplied continuously, and zone separation can be achieved. In another procedure, water is dropped on a colored spot on a filter paper, resulting in separation in concentric zones [189].

Mobile Phases. Suitable mobile phases are critical for dye separation by paper chromatography (Table 13); these phases are sometimes chemically or physically unstable and change with time. Good reproducibility can only be achieved with mobile phases of about equal age. Accordingly, all mobile phases should be renewed regularly.

After separation of the dye from any substrate that is present [169–172], [203], [204], 0.25 – 2 % dye solutions are used for paper chromatography. Water is the preferred solvent; organic solvents are used only if water solubility is inadequate. The ascending method is preferred for determination of the most suitable mobile phases [186], [205]. The rate of migration is measured by the R_f value [186], which is only approximately constant but gives a guide to the order of separation [206–208]. It is often possible to improve separation by altering the pH [115], [119].

Paper chromatograms are evaluated in reflected and transmitted daylight and in UV light. Fluorescent substances are often present in commercial dyes as residues of intermediates.

It is never safe to conclude that a dye is homogeneous because its chromatogram shows no separation. The characterization of dyes on the chromatogram is supported by color tests [115], [119]. Paper chromatography can also be used in quantitative analysis.

The sensitivity of the method depends on the sharpness of the zone and the shade of the color spot. The limit of detection is between 0.5 and 1 % with yellow dyes and between 0.05 and 0.1 % with blue dyes. Fluorescent compounds can be detected at 1 part in 100 000 parts of the principal dye. In favorable cases, it is possible to detect as little as 1 ng (10^{-9} g).

5.3. Thin-Layer Chromatography [209–211]

For many years, dyes have been separated by adsorption on layers of alumina between two thick glass plates, the top one of which has a hole in the center [212]. This method, called disk chromatography, is a predecessor of thin-layer chromatography [213], [214].

In thin-layer chromatography (TLC) separation is accomplished on adsorbents spread on glass, aluminum, or plastic plates in a layer ca. 100 – 250 μm thick. Commercially prepared plates have the advantage of uniform thickness and they can be cut to the desired size. The separation is effected in glass chambers filled with mobile phase to a depth of ca. 1 cm (Table 14). The thin-layer plate is placed vertically in the chamber, and within 1 h the mobile phase usually rises far enough for separation. The general procedure resembles paper chromatography, but smaller specimens usually serve well.

To avoid interference during chromatography, the applied spots must first be dried in air. For separation of larger quantities, the solution is applied in a streak over the full width of the plate [209]. Plates with layer thicknesses up to 5 – 7 mm separate milligram quantities, which are useful for comparing IR spectra [210] or other spectroscopic techniques.

Silica gel [*7631-86-9*] is the substrate most widely used for dyes [215], [230], [233] – 235]. Gypsum [*13397-24-5*] is often added to improve adhesion; the product is designated Silica Gel G. Silica-based substrates have been extended to high-performance thin-layer chromatography (HPTLC) [237], [238], which provides higher resolution and speed. The coatings resemble packings used in high-performance liquid chromatography (HPLC).

Table 13. Mobile phases for paper chromatography of dyes

Dye class	Mobile phases	Reference
Acid dyes	ethyl acetate – pyridine – water (70 + 25 + 20), (35 + 25 + 20)	[190]
	trisodium citrate – 25 % aqueous ammonia – water (2 g + 20 + 80)	[191]
	1-butanol – acetic acid – water (50 + 10 + 20)	[190]
	ethyl acetate – acetic acid – water (80 + 20 + 20)	[190]
	1-butanol – ethanol – water – ammonia (100 + 20 + 44 + 1) or (20 + 10 + 10 + 10)	[192], [193]
	1-butanol – formic acid – water (100 + 24 + 36)	[190]
Direct dyes	isoamyl alcohol – pyridine – 25 % aqueous ammonia (10 + 13 + 10)	[194]
	1-butanol – pyridine – water (20 + 30 + 30)	[195]
	benzyl alcohol – dimethylformamide – water (30 + 20 + 20)	[196]
Reactive dyes	1-butanol – acetic acid – water (80 + 10 + 10) or (20 + 10 + 50)	[197], [198]
	disodium hydrogen phosphate – ammonia – water (2 g + 20 + 80)	[199]
Basic dyes	ethanol – ammonia – water (20 + 20 + 10);	[200]
	chromatography paper impregnated with lauryl alcohol	
	tetrahydrofuran – ammonia – water (10 + 4 + 7); separation using acetyl paper	[107, p. 162]
Disperse dyes	ethyl acetate – tetrahydrofuran – water (1 + 8 + 8); separation using acetyl paper	[201]
	tetrahydrofuran – ammonia – water (10 + 4 + 7); separation using acetyl paper	[201]
	chloroform – acetic acid – water (10 + 10 + 10); separation using paper impregnated with silicon	[196]
Vat dyes	tetraethylenepentamine – water – hydrosulfite (10 + 100 + 10)	[202]

Table 14. Mobile phases for thin-layer chromatography of dyes

Dye class	Mobile phases	Adsorbent	Reference
Acid dyes with sulfo groups	1-butanol – ethanol – water – acetic acid (60 + 10 + 20 + 0.5)	silica gel G ∗	[215]
	butyl acetate – pyridine – water (30 + 45 + 25)	silica gel G	[216]
	1-butanol – acetic acid – water (20 + 10 + 50) upper phase	silica gel G	[217]
Acid dyes with carboxyl groups	1-butanol – ethanol – 25 % aqueous ammonia – pyridine (40 + 10 + 30 + 20)	silica gel G	[218]
	toluene – acetic acid (65 + 35)	silica gel G	[219]
	ethyl acetate – pyridine – water (60 + 30 + 10)	silica gel G	[215]
Direct dyes	1-propanol – 25 % aqueous ammonia (60 + 30)	silica gel G	[220]
	1-amyl alcohol – pyridine – 25 % aqueous ammonia (10 + 10 + 10)	silica gel G	[220]
	1-butanol – acetone – water (50 + 50 + 30)	silica gel G	[221]
Reactive dyes	1-propanol – ethyl acetate – water (60 + 10 + 30)	silica gel G	[222]
	butyl acetate – pyridine – water (20 + 20 + 10)	silica gel G	[223]
Metal complexes 1 + 2, without sulfo groups	methanol – 25 % aqueous ammonia (95 + 5)	micropolyamide F 1700	[224]
	methanol – monoethanolamine (95 + 5)	micropolyamide F 1700	[201]
	toluene – acetic acid (70 + 30)	silica gel G	[224]
Basic dyes	chloroform – 2-butanone – formic acid (6 + 8 + 1)	silica gel G	[225]
	1-butanol – acetic acid – water (50 + 10 + 20)	silica gel G	[226]
	1-propanol – formic acid (80 + 20)	silica gel G	[227]
	carbon tetrachloride – methanol (4 + 1)	polyamide	[228]
Disperse dyes	toluene – acetone (20 + 1)	silica gel	[229]
	toluene – acetic acid (90 + 10)	silica gel G	[201]
	chloroform – methanol (95 + 5)	silica gel G	[226]
	toluene – ethanol – 25 % aqueous ammonia (850 + 150 + 15)	silica gel G	[201]
Solvent dyes	benzene	silica gel G	[214]
	toluene – acetic acid (90 + 10)	silica gel G	[201]
Organic pigments without sulfo groups	chloroform – xylene (30 + 10)	silica gel G	[230]
	dichloroethane	silica gel G	[231]
	benzene	silica gel G	[232]
	hexane – benzene – pyridine (5 + 20 + 15)	silica gel G	[226]

∗ Silica gel G: gypsum added for better adhesion

Figure 16. Separation of reactive dyes and their derivatives by HPLC
Packing material Hypersil ODS; Particle size 5 μm; Column 100×5 mm; Mobile phase 62.5 % acetonitrile in water; Flow rate 2 mL/min; Detector UV/visible at 420 nm; Temperature 40 °C; Water phase contains 0.5 g of cetyltrimethylammonium bromide per 100 mL as ion pairing agent.

The mobile phase can be selected by carrying out preliminary experiments using a series of solvent mixtures of increasing polarity (elutropic strength) [214]. Ideally, distinct, well separated zones should be obtained.

Selection can be simplified by reference to various publications [215], [218], [221], [222], [239–241]. Some mobile phases are listed in Table 14.

5.4. High-Performance Liquid Chromatography (HPLC)

High-pressure liquid chromatography, later called high-performance liquid chromatography, was developed in the early 1970s and was soon applied to dyes, where its value was greatly increased by the introduction of reverse-phase systems [242–244]. Developments utilizing stationary phases of particle sizes $< 5\ \mu$m have resulted in higher separation capability and speed [237], [238].

Mobile Phase. As with TLC, efficient separation depends on the appropriate selection of the mobile and stationary phases, but with the added facility of programmable mobile phase composition.

Reverse-phase HPLC, which uses surface modified supports and is the preferred method for polar compounds, utilizes binary (or sometimes ternary) eluents containing water, acetonitrile, tetrahydrofuran, or methanol.

Example of Dye Separation by HPLC. Figure 16 shows the chromatographic separation of a series of reactive dyes of similar structure. The area under each peak is proportional to the quantity of the component. The retention

Figure 17. ^{13}C NMR spectrum of azo dye **26**, broadband proton-decoupled

Figure 18. ^{1}H NMR spectrum of azo dye **26**

time is characteristic of the component in this reverse-phase HPLC analysis.

Allied techniques such as ion chromatography have also been of value in the detection and measurement of ionic diluents or impurities and in identifying the cations present. For the separation of dyes from impurities or additives, HPLC has been extended to preparative liquid chromatography with column diameters of 2.5 cm.

6. Spectroscopic Measurements

6.1. Nuclear Magnetic Resonance (NMR)

This technique is perhaps the single most useful means of structure determination. Modern instruments operating at a proton frequency of 90 – 400 MHz provide resolution capable of distinguishing between closely related compounds. Mass spectrometry can provide molecular mass and elemental composition.

Fourier transform NMR with ^{13}C and ^{19}F probes is valuable for investigating highly condensed aromatic or proton deficient molecules [245–247].

Example of Structure Elucidation. Disperse dye **26** was examined both by ^{1}H NMR and ^{13}C NMR. The spectra are shown in Figures 17 and 18. They are fully consistent with the structure of **26**; in fact, the ^{13}C NMR spectrum shows the peaks for each single carbon atom.

The identification of the dye can be confirmed by its synthesis or by an accurate measurement of the molecular mass by high-resolution mass spectrometry. Colors and intermediates containing other suitable nuclei such as N, P, or F can also be identified using appropriate probes.

6.2. Mass Spectrometry (MS)

In the past, mass spectrometry has been limited by the involatile nature of most dyes, but fast atom bombardment (FAB) ionization has produced high-quality mass spectra on a wide range of compounds previously regarded as intractable. Both positive and negative ions are produced, but the latter are preferred for structure elucidation because they yield more abundant fragment ions and fewer interfering ions at low mass [248], [249]. HPLC can be coupled with MS for identification of mixtures.

6.3. UV-Visible Spectrophotometry

This technique has always been of great value to manufacturers and users of dyes. Scanning instruments increased the scope for mixtures, but the real impact has been in the use of differential spectrometry, in which a microprocessor incorporated into the instrument can produce first, second, or even higher-order derivative spectra. Mixtures of colors can be measured and information provided on their exhaustion profiles (see also Chap. 3).

1. Introduction

Throughout history, mankind has endeavored to change the appearance of base metals by applying metallic coatings of various types, either for decoration, or to enhance their value. There seems to be evidence that the Egyptians used a crude galvanic process for gilding and that some of the gold bars extorted by the Spanish from the Incas as ransom were actually lead gilded by the amalgam process; the application of gold leaf to various substrates has been an accepted method of decoration from the Middle Ages to the present.

Since early times, too, the ravages of corrosion have been evident, and efforts were made to alleviate this destructive process by the application of hot-dip coatings or cladding of metals by impacting or heating the parts with powdered metal as in Sheradizing (→ Metals, Surface Treatment).

For the most part, although electroplating became common practice as soon as practical direct current generators were developed, it remained more art than science until true scientific research was undertaken in the mid 1930s. The impact of World War II produced a tremendous surge in this research, which has continued to the present day.

As a result, great progress has been made in understanding the fundamentals underlying the plating process. This has brought with it the development of improved solutions with controlled plating characteristics so that the physical properties of the deposits may be controlled; new types of solutions and plated alloys; plated composites; and many nonaqueous and nonelectrolytic methods of depositing desired coatings.

An important consequence of the new mastery of plating theory and technique has been the general realization that the plated coatings are not just a cosmetic treatment applied as the final step in manufacturing, but an engineering tool that can be used to improve the performance of the product, reduce cost, or enable the product to resist particularly severe environments. The selection of the proper coating has therefore become part of the engineering design process.

The plating process is an electrochemical process that passes an electrical current through a solution containing metallic ions. These ions are reduced and deposited on the cathode as a metallic coating. If the anode is made of the metal being deposited, it dissolves to replenish the metallic ions in solution. If it is an insoluble anode, periodic additions of metal salts must be made to the solution to maintain the metal content.

The process is controlled in a general way by the usual electrical and electrochemical equations: Ohm's Law, Faraday's Law, and the equilibrium equation for the standard single electrode potential. The flow of current in the tank responds to the requirements of Ohm's Law in that the flow of current is directly proportional to the applied voltage, and inversely proportional to the resistance of the system. However, this is not a linear relationship. The system is a dynamic one, and the internal resistance in the tank is affected by many factors.

The quantity of metal deposited follows the principle of Faradays's Law in that the mass of metal deposited is directly proportional to the current flow, the time and the relative atomic mass of the metal, and inversely proportional to the oxidation state of the metal in solution. Here too, the relationship is not linear. It may be affected by competing reactions whose share of the current flow may depend on the voltage and the rate of current flow.

The single electrode potentials determine the minimum voltage required for plating, and the distribution of the available current among the various competing reactions.

2. Glossary of Terms

A large spread exists in the educational levels of even reasonably well-trained electroplating professionals. There is therefore considerable variation in the definition of the terms used. These definitions are frequently at variance with the definition used by electrochemists. The definitions that follow are those that would be accepted by the majority of knowledgeable, practicing electroplaters.

Rack Plating. The plating process in which the parts to be plated are fastened to fixtures that are carried through the plating process either manually or by some automatic mechanism. The parts are held to the fixtures by pressure contacts

that also serve to carry the required current to the parts.

Barrel Plating. The plating process in which the parts are loaded into a plastic perforated container, generally hexagonal in shape, which is then carried through the process either manually or by some automatic mechanism (Fig. 1). While in each of the solutions, the barrel is rotated so that the parts slowly tumble in the barrel and are all exposed to the plating action. Current is supplied through various types of contacts into the mass and transferred from piece to piece by the contact made during rotation. This process is especially useful for small screw machine parts and stampings.

Brush Plating. This is also sometimes called *spot plating*. Not all plating has to be carried out by total immerson. Techniques have been developed for selective plating using portable equipment and anodes surrounded by absorbent material that do not require immersion of the part. The anode is saturated with solution and rubbed over the surface of the area to be plated. Because of the movement and the slight abrasive action of the absorbent material, very high localized currents may be used. Special plating solutions are required. The entire package of equipment and solutions, as well as instruction in operation, are supplied as proprietary units. The method is not generally recommended for production but is used for repair of worn or defective parts, e.g., in situ repair of worn printing rolls or ship propeller shafts, and the plating of parts too large for immersion techniques or objects that must be plated in place; e.g., several large statues in Washington, D.C., were refurbished by gold brush plating.

Pulse Plating. The current used for plating does not always have to be applied as a continuous flow. In pulse plating, the current is applied in short bursts of high intensity followed by a period in which no current is applied. The cycles are described in terms of the ratio of On time to Off time, the *duty cycle,* which is usually expressed as a percentage, and the *frequency,* which determines the time length of each cycle. By varying the duty cycle and the frequency, desirable alterations to the physical characteristics of the deposits may often be obtained. Although the current is on for only a percentage of the total time, the current densities during the On time are sufficiently high that the average current density is usually close to or even higher than the current density recommended for regular direct current. Not all metals can be deposited using pulse plating since some metals do not tolerate variations in the applied current (*ripple*) above 5 to 10 %.

Immersion Deposits (see Section 10.1). Deposits that form on a surface by a simple replacement reaction. If a metal is immersed in a solution that contains ions of a less reactive metal, the metal immersed dissolves, in the process acting as a reducing agent for the metal ions in solution, which deposit on the surface of the immersed metal, e.g.,

$$Cu^{2+} + Fe \longrightarrow Cu^{0} + Fe^{2+}$$

The process continues until a completely continuous coating has been formed on the substrate, after which no further action occurs. The immersion coating is usually of poor structure and lacks adhesion to the substrate.

Conditions can be adjusted in some solutions so that coatings with desirable characteristics form, and such solutions are used for special purposes, e.g., a copper sulfate – sulfuric acid solution for producing a *copper liquor finish* on steel wire to act as a lubricant in drawing (see page 47). Many plating solutions form such coatings on some metals that are to be plated, with the result that the subsequently plated layer has no adhesion. These metals must be preplated with a thin layer of a nonreactive metal. The solutions used to apply these preliminary coatings are generally referred to as strike solutions.

Strike Solution. A strike solution is one that has been designed to plate thin deposits at relatively high current densities and without forming immersion deposits. The solution is used only to produce the initial thin layer of plating to completely cover the substrate. The metal used may be the same as the subsequent plated deposit, or may be different than, but compatible with, the subsequent plated layer. Typical examples: a cyanide copper strike on zinc-base die castings or on steel before bright acid copper, a silver strike on copper before silver plate, a cadmium or tin strike on cast iron before cyanide zinc plating.

Figure 1. Schematic drawing of a plating barrel

Current Density (C.D.). The rate of current flow at any point on the part or parts being plated. This is usually expressed as amperes per square decimeter (A/dm^2) or amperes per square foot (A/ft^2). The conversion factor A/dm^2 to A/ft^2 is 9.29. Because current density is a relatively inexact measurement, however, it is common practice to use a conversion factor of 10.

Since measurement of the current density on small areas is difficult or impossible, current density is usually given as an average for the area being plated. There are now available meters that can be placed in the solution near the parts being plated to determine the current density over a relatively small area. While these meters do not measure the current density at a point, they provide more exact figures than those obtainable by dividing the total current by the total area being plated. If the parts are sufficiently large, current in the high and low current density areas can be determined.

Current Distribution. Two terms are used in the discussion of current distribution: *primary current distribution* and *secondary current distribution,* and some confusion exists as to the exact meaning of each term.

The original research into current distribution used nonconductive models of parts that were charged with static electricity. The potential at various points on the surface was then determined and related to the current that would flow if this potential existed in a plating cell. The resulting distribution of current was considered to be the primary current distribution. The secondary current distribution was then considered to be the current distribution that occurred during the actual plating operation. This included the effects of tank configuration, including rack placement, tank walls, anode placement, and the effects of polarization at both the anode and the cathode. Some electroplaters still use these definitions.

As instrumentation improved, and computers became more sophisticated, it became possible to model complete tank configurations and estimate the potentials within the tank. Brightener systems also became more complex and had greater influence on current flow. Researchers began to define primary current distribution as that which would exist in the absence of current flow as a result of the physical arrangement in the plating cell, and the secondary current distribution as that which would exist during actual plating including the effects of polarization and various brightener influences.

Most of the available information is empirical and unquantified. Further, the dynamic changes between primary and secondary current distribution vary with the brightener system, the solution composition, and operating conditions. However, an experienced plater can markedly improve the current distribution on even extremely

complicated pieces by the judicious use of supplementary anodes, shields, and rack positioning.

Deposition Potential. This is another case where the average plater is at odds with the electrochemist. For the average plater, the deposition potential is defined as the electrical potential that is just sufficient to initiate electrodeposition of the metal in question. This potential is in part a function of the solution composition, particularly the ionic concentration of the metal at the interface, and therefore is a dynamic quantity changing in response to changes in temperature, plating rate, agitation, and degree of polarization. The term overvoltage is frequently used interchangeably for deposition potential.

Hydrogen Overvoltage. Generally this term is used for the deposition potential of hydrogen at the cathode. It varies with the substrate making initial deposition on some metals difficult from some solutions. For example, the hydrogen overvoltage on graphite is extremely low. In a cyanide zinc plating bath, the deposition potential of zinc is ca. one volt. Cast iron has graphite exposed at many points on the surface. It is therefore almost impossible to plate cast iron parts in a cyanide zinc solution since hydrogen deposits preferentially. If, however, the cast iron is given a preliminary strike of cadmium or copper to cover the graphite, zinc plating proceeds normally. Deposition of hydrogen with the metal being plated affects efficiency and may produce hydrogen embrittlement of the substrate.

Hydrogen Embrittlement. Hydrogen that is codeposited with the metal being plated or that is formed during acid pickling or cleaning procedures may be absorbed by the substrate. When this occurs, the hydrogen may eventually collect at crystal interfaces at points of stress, develop extremely high pressures, and cause brittle failure of the material. A number of different mechanisms have been postulated for this occurrence, but no one mechanism has been firmly established as the absolute cause. Indeed, it is possible that under varying conditions, several different mechanisms may be operating concurrently. However, the problem is particularly severe with high strength steels. Research work to date indicates that, before plating, susceptible substrates should be stress relieved at temperatures close to the last heat-treating temperature for periods up to 24 h, the plating cycle should be designed to offer the minimum possible exposure to hydrogen, and the parts should be subjected to a postplating baking operation at a temperature approximately 28 °C below the temperature of the final heat treating step for periods of up to 24 h.

Polarization Effects. Polarization is the change that takes place in the system as a result of the current flow. Films will generally form at both the anode and cathode surfaces. These polarization films generally have a much higher resistance than the body of the solution and vary in thickness with the current density. The cathode polarization film therefore affects current distribution and efficiency. Chemical changes within the film may change the physical characteristics of the deposit. As a result of secondary reactions, the pH of the polarization films may be grossly changed, producing additional effects. The thickness of the polarization films depends on current density, temperature, and agitation.

At the cathode, depletion of the metal ions being plated increases the absolute value of the deposition potential of the metal. If this potential rises above the hydrogen overvoltage for the process, hydrogen codeposits, with a loss of plating efficiency and an increase in the pH of the film. If the pH change is sufficient, metallic hydroxides may codeposit with the plated metal, disrupting the crystal structure and producing the coarse, granular deposits generally referred to as *burning*.

Electrophoretic attraction of selected colloids into the film may increase film viscosity by a large factor. Advantage is taken of this phenomenon to alter the deposited film and produce leveling and brightening actions on the deposit.

At the anode, reactions may occur as a result of the increase of concentration of the metal ions in the polarization film. Secondary reactions may produce oxidizing materials that destroy brightener components and/or form highly resistant oxides on the anode surface resulting in *passivation* of the anodes with a loss of current carrying capability. Advantage is taken of this in alkaline tin plating to ensure that the tin

dissolves in stannic form (Sn^{IV}) rather than as stannous tin (Sn^{II}).

Efficiency. Efficiency is the ratio of the actual amount of metal deposited on the substrate to the theoretical amount calculated by Faraday's Law. It is usually expressed as a percentage. The efficiency is influenced by the difference between the dynamic deposition potential of the metal being deposited and the potentials of the secondary reactions, particularly the deposition potential for hydrogen. Efficiency is therefore affected by polarization and hence by all the factors that also affect polarization.

Covering Power. Covering power is the ability of a solution to deposit metal into recesses or holes where the current density is low. It is basically controlled by the deposition potential for the metal being plated under the operating conditions of the solution being used. Numerous ingenious ways of measuring covering power have been developed. However, they are all empirical and not easily quantified.

Throwing Power. Throwing power is a measure of the ability of the solution to plate a greater thickness of metal into the low current density areas than would be predicted from the primary current distribution. If the ratio R = actual plating thickness/predicted thickness is greater than one, the throwing power is said to be positive; if smaller, negative. Solutions that are highly complexed with considerable polarization generally have positive throwing power. In fact, certain cyanide zinc solutions plate with ratios as high as 1.25. Uncomplexed solutions with moderate polarization have little or no throwing power (R ca. 1.0), while a few solutions with deposition reactions consisting of several dependent steps, e.g., chromium plating from hexavalent solutions, have negative throwing power.

An approximation of the throwing power of a solution may be made by plating a panel in a plating test cell such as the Hull Cell, calculating the deposit thickness expected on the basis of the primary current distribution at a number of points along the panel and measuring the actual thickness obtained at these same points. If the low current density areas show $R > 1$, throwing power is positive. It is also possible to obtain absolute values for the throwing power of a solution using the Haring test cell. However, both test procedures provide results valid only for the conditions under which the test was run, and any change in these conditions may also change the results. It is difficult therefore to relate the results of such tests to the results obtained with production parts.

Investigations into the mechanisms of brightening and leveling have revealed that the throwing power mechanism exists on two dimensional levels. Furthermore, these two levels appear to have no relationship to each other. Two different terms are therefore used, macro-throwing power and micro-throwing power.

Macro-throwing power is used to describe the ability of a solution to alter the ratios on a gross scale. Macro-throwing power measures the ability of a solution to plate into very low current density areas of a part, i.e., into holes, recesses, corners, etc.

Micro-throwing power is used to describe the ability of a solution to alter the ratios on a micro scale. Micro-throwing power measures the ability of a solution to plate into fine defects on the surface, such as scratches, polishing lines, pores, pits, etc. Micro-throwing power is an essential requirement for leveling or smoothing properties in a solution.

A solution may have good macro-throwing power and brightness without having micro-throwing power or leveling capability. Conversely, it is also possible for a solution to have excellent micro-throwing power and leveling, as well as brightness, without having good macro-throwing power.

Auxiliary Electrodes. Supplemental electrodes that are used to bring current to normally low current density areas (Fig. 2). Also referred to as "inside anodes," "internal anodes," or "conforming anodes." The electrode material may be the same as the metal being plated or may be an inert material, such as lead, stainless steel, titanium, or platinized titanium, depending on the nature of the plating solution. Such electrodes are mandatory for hard chrome plating internal diameters and complex dies. The internal anode is mounted on, but insulated from, the rack holding the parts and is connected to the anode bar, which provides the current. In some cases, a small rheostat may be connected in series between the internal anode and the anode bar to

Figure 2. Auxiliary anode

Figure 3. Bipolar anode
The bipolar anode and anode bar have no direct contact.

permit regulation of the current drawn by the internal anode.

Bipolar Electrode. A passive electrode placed between the parts to be plated (cathode) and the anode (Fig. 3). The end closest to the anode, also called the collector, becomes negative and is plated, collecting current that flows through the electrode to the end nearest the cathode, making it an anode that then functions the same as an auxiliary anode. The essential requirement for the functioning of this type of electrode is that the distance from the anode to the collector plate plus the distance from the bipolar anode to the area to be plated is less than the distance from the anode to the parts. Bipolar anodes have the advantage over auxiliary anodes that no direct contact with the anode bar needs be made. They have the disadvantage that the metal plated on the collector is wasted unless it can be stripped off and used as anode material.

Bipolar electrodes may also form accidentally and cause undesirable effects. There are three common cases:

1) In unlined conductive tanks, the distance from the anodes to the tank wall plus the distance from the tank bottom to the bottom parts on a rack may be less than the distance from the anodes to the work. The bipolar electrode that then forms may supply excessive current to the lower parts on the rack (Fig. 4). The cure is to insulate the tank, or insert a *shield* between the anodes and the tank wall or bottom.
2) In a lined tank, parts that fall into the tank and are allowed to remain there may form a bipolar electrode (Fig. 5). Additionally, the portion of the part that becomes the anode may dissolve, contaminating the solution. This is a frequent problem when nickel plating zinc-base die castings, resulting in severe contamination of the solution with copper and zinc. The cure is to regularly remove any parts that fall off the racks.
3) On automatic plating machines, a rack being lowered into the tank may temporarily become a bipolar electrode until it makes contact with the cathode bar. Hazing, clouding, or even peeling of the area that acts as the collector during this period may result. If this condition is suspected, provisions should be made for *live entry* of the rack into the solution, i.e., a connection with the cathode bar should be made before entry.

Figure 4. Bipolar short in an uninsulated tank
A bipolar short occurs when $C > A + B$.

Figure 5. Bipolar short in an insulated tank
A bipolar short forms if $C > A + B$: the surface of fallen parts adjacent to the anode becomes cathodic (−), while the surface nearest the parts being plated becomes anodic (+).

Shields. Nonconductive materials placed between the anode and the parts to be plated in such a way and of such shape that they restrict the area available for current passage and therefore alter the current distribution and control the buildup of plating on high current-density areas. Shields may also be used between anodes and the walls of unlined tanks to prevent the formation of bipolar electrodes through the tank walls. Wire-reinforced glass is frequently used for this purpose (see Fig. 6)

Figure 6. Use of shields to protect high current-density area

Composites. Composites are electrodeposited coatings that consist of a metallic electrodeposited matrix that surrounds and incorporates into its structure a nonmetallic material that has been suspended in the solution. The physical characteristics of the final coating are determined by the nature of the incorporated material and the ratio of incorporated material to metal. Materials that can be incorporated include fine beads of plastic, such as Teflon for added lubricity; diamonds and silicon carbide to form abrasive coatings or non-slip surfaces; microscopic particles of aluminum oxide in nickel to alter the electropotential under corrosive conditions and provide added protection in the multilayer nickel system for protecting steel and zinc-base die castings; and many other combinations.

Electroforming. Electroforming is the process of producing products by plating, such as compact recording discs, radar waveguides, pen parts, aircraft parts, complex bellows, and jewelry. Extremely complex configurations can be economically produced. A mandrel conforming

to the desired shape is prepared and plated with the metal or alloy required to the necessary thickness. If the shape allows, the part may be removed and the mandrel reused. More complex shapes use expendable mandrels made of aluminum, wax, or a low-melting bismuth – lead alloy. The mandrel is then melted or dissolved out of the finished part. Plating thickness may be as great as 6 mm (0.250″).

Alloy Plating (see Chap. 9). When two or more metals are present in the electrolyte, all of which are capable of being deposited from solution, they codeposit to form an alloy, provided the deposition potentials are sufficiently close together. The composition of the deposited alloy depends on the differences between the deposition potentials and the relative concentrations of the metals in solution. Since the polarization film affects the deposition potentials, and since the degree of polarization is affected by the current density, the composition of the deposited alloy may vary with current density. The extent of this variation depends on the diffusion characteristics of the metal ions, the amount of agitation, and the difference in the deposition potentials. Typical alloy coatings include brass, cyanide being used to control the deposition potentials of zinc and copper; bronze, cyanide being used to control the deposition potential of copper and sodium hydroxide to control the deposition potential of tin; nickel – iron, where only minimal control of the iron is needed; and many others. Ternary alloys are also possible, although in general the problems of solution and operational control restrict these to special applications.

Many alloy coatings are not necessarily recognized as alloys. The *hardeners* often used to modify the characteristics of gold deposits for various electronic uses are actually materials that are codeposited to form alloys. Similarly, metallic brighteners, such as cadmium in nickel solutions, codeposit to form an alloy that, although extremely low in cadmium, has a crystal structure that produces bright deposits.

3. Protection Against Corrosion

Metals may corrode in several different ways. Gases in the atmosphere may react with the surface of the metal to form a compound such as an oxide, a sulfide, or a carbonate. If the compounds formed by these reactions are water soluble, subsequent exposure to rain or other liquids may wash the salts away, allowing the corrosion to continue. If the compounds are insoluble and essentially nonporous, they may form a protective coating to hinder further corrosion.

Acid or alkaline materials may in the presence of moisture directly react with the surface, releasing hydrogen and forming salts with the substrate. Once again, depending on the solubility of the salts formed, the result may be additional corrosion or some protection. Acid rain has contributed greatly to the corrosion of metallic structures. The widespread use of salt to control ice and snow on roads and highways has resulted in severe corrosion of the reinforcing rod in the concrete and destruction of the supporting structures of many bridges and elevated highways.

Sooner or later, however, almost all corrosion becomes galvanic in nature. This may be because of the contact between dissimilar metals, stress within the metal, segregation of alloying components within the metal, or differential availability of oxygen as a result of dirt collection or salt formation on the surface. The only requirements for the progression of galvanic corrosion are the existence of a potential difference between points and the presence of enough moisture to allow the corrosion current to flow. This form of corrosion can be particularly damaging because it may be highly localized and penetrate the substrate in the form of deep pits.

Protection against corrosion may be obtained by several procedures. If the area to be protected can be covered by a layer of nonreactive material that is impervious to moisture and that completely encapsulates the surface to be protected, corrosion cannot occur.

Plated metals may protect surfaces in one of two ways. If the plated metal is less noble than the metal to be protected, any corrosive condition causes the plated coating to dissolve in preference to the substrate. The more active metal may even be able to protect areas that are no longer covered. Zinc and cadmium protect steel and brass by such a mechanism. Because of this characteristic, porosity in such a coating, while it reduces the life of the coating, does not produce catastrophic corrosion in the base metal.

A metal that is more noble than the substrate can only protect the substrate if the coating is completely encapsulating and pore-free. Such is the case for copper and nickel on zinc-base die castings or steel. Any porosity in the coating results in severe pit corrosion of the substrate. Furthermore, this corrosion also spreads laterally causing additional loss of the plated coating and additional corrosion.

To effectively prevent corrosion, multilayered nickel and chromium coatings are applied to automobile hardware. The several layers are deposited using different additives so that their electrochemical activities are different. Such corrosion as does occur is restricted to the plated layers, thus allowing continued protection of the substrate.

4. The Plating Process

The simplest concept of the plating process is as an electrochemical process in which metallic ions in a supporting solution are reduced to the metallic state at the cathode, forming the plated film. At the anode, metal may be oxidized from the metallic state to the ionic state, thereby replenishing the metallic ion content of the solution. The ions, released at the anode, migrate through the solution to replenish the cathode film. The electrons released by the oxidation of the metal at the anode, travel through the external circuit to the cathode. A driving potential (emf or applied voltage) to force the reaction to proceed must be provided by an external source. This source could be a battery, a generator, or a d.c. power supply (commonly referred to as rectifier). In modern practice, rectifiers are used almost exclusively.

The actual process is considerably more complicated. The dissolved metal ions are frequently held not in simple ionic form but as complexes of various types, often carrying a negative charge, so the migration tendency is not toward the cathode where they are needed, but back toward the anode increasing the concentration polarization. Some form of supplemental solution movement is needed to ensure adequate migration rates to replenish the cathodic film.

Immediately upon the application of current, a capacitive film, generally referred to as the zeta layer, is formed closely adjacent to the cathode. The incoming metallic ions are discharged to the elemental state at the surface of this layer. The atoms of metal then diffuse through this layer to the substrate surface, where they seek to establish themselves as part of the growing crystal lattice. The incoming atoms enter into the lattice in such a way as to reduce the overall free energy of the surface.

The *initial layer* on the substrate forms as submicroscopic crystallites, which grow by accretion of the incoming atoms both horizontally and vertically until a continuous coating is formed. The number and distribution of the crystallites in the initial nucleation of the surface is strongly affected by the surface preparation and in turn affects the crystal structure of the subsequent coating. Addition of selected organic materials to the electrolyte can modify the growth habit of the crystallites, restricting growth to the horizontal plane in preference to vertical growth, speeding the completion of the initial covering layer, and refining the crystal structure of the deposit. Incorporation of organic and inorganic additives in the electrolyte can be used to block selected sites on this growing lattice and force the incoming atoms into a desired growth pattern, thus producing leveling, brightness, stress relief, or other desired characteristics in the deposit.

The beneficial effect of these additives is such that in modern plating practice unmodified solutions are seldom used. Historically, the initial discovery of additive materials was an empirical process and developed as a result of the experimentation of practical platers whose scientific training was minimal. Subsequently, supply houses specializing in meeting the needs of platers recognized the need for improved solutions and mounted a determined scientific effort to develop solutions that would meet the increasingly stringent requirements of the plating industry. The result was the development of a complex and extensive series of brighteners or addition agents that could produce deposits that were bright, smooth, hard, soft, especially corrosion resistant, or with some other desired characteristic. From the original single or double type additive, e.g., the use of cadmium chloride and yellow dextrin for bright barrel plating of nickel, these additive systems have developed into extremely complex mixtures with as many as a dozen different materials in vari-

ous concentrations, some of which are extremely low. In many cases, the effective ingredient is a specially manufactured organic chemical that has been reacted under carefully controlled conditions to produce the active agent. Many of these are patented and have been developed by supply houses, which sell them to the trade as proprietary mixtures. While the composition of many of these additives can be inferred from the patents or other published literature, the difficulty of properly preparing the mixtures or some of their ingredients has militated against preparation of the materials by individual platers' homebrew, and therefore proprietaries are used almost exclusively.

With continued electrolysis, a polarization film usually forms. Since this film is thicker in the high current density areas, the added resistance of the film in those areas forces the current flow into areas of normally lower current density, producing an improvement in the throwing power of the solution. If the formation of this film increases the deposition potential of the metal sufficiently, hydrogen is codeposited with the metal, the efficiency falls off, and the throwing power improves still further.

4.1. Design for Plating

Because of the complex nature of the plating process and the way plated coatings can be used to restrict corrosion or impart other desirable properties, there are substantial benefits to be gained from having a plating expert as part of the design team. There are several aspects belonging to the design process:

1) Selection of the proper coating. This involves an evaluation of the corrosive environment to which the part will be exposed, the purpose to be served by the coating, and the nature of the substrate material. The expected life of the part, and the effects in danger and cost of a failure of the part, must be considered. The placement of the plating operation in the sequence of manufacturing may be important.
2) Part shape. Sharp corners, deep recesses, blind holes, and a number of other dimensional conditions that affect the current distribution may make plating difficult or limit the type of solution that can be used. If parts are to be rack plated, the design must make provision for easy and secure racking. If parts are to be barrel plated, design features that eliminate nesting or sticking should be incorporated.
3) Dimensional limitations. The thickness of the plated deposit must be added to the original dimensions of the part. Because of the effects of current distributions and throwing power, these dimensional changes are affected by the location of the critical area on the part. An experienced metal finisher can often accurately estimate what these effects may be and suggest either dimensional allowances be made or design effective racking and shielding procedures to hold the changes to controlled limits. This can be illustrated by the approximate effects of a deposit on the dimensions of a threaded fastener or threaded hole.
   The approximate changes to be expected are: major diameter, 2 – 2.5 times the plate thickness; root diameter, 1 – 1.5 times the plate thickness; pitch diameter, ca. 4 times the plate thickness. For an external thread the dimensions are increased by this amount; for an internal thread there is an equivalent decrease. It is entirely possible, therefore, that a fastener that mated perfectly with a threaded hole before plating will be out of tolerance after plating. Projecting threaded fasteners may receive even greater thickness of plating and have to be shielded.
4) Production sequence. The ideal place in the manufacturing sequence for the finishing operation may need consideration; e.g., it may be more economical to plate certain parts before assembly rather than after.

All of these factors must be considered and optimized to produce the desired quality parts at the lowest possible cost.

4.2. Control

Although there are numerous variables in the process, routine operation is attained with surprisingly little control. Routine chemical analysis of the composition of the solutions and careful control of operating temperatures for all solutions often suffices. For more critical opera-

tions, control of the concentrations of the addition agents may be required. For specification work, routine thickness checks on finished parts on either a random or statistically controlled basis may be needed. Statistical control of thickness is especially important in the barrel plating of gold in order to hold costs to a minimum. For especially critical work, such as aircraft maintenance and repair, the space program, or nuclear work, a much more sophisticated control procedure may be required.

4.3. Impurities

Impurities that can affect the character of the deposit include metallic ions, organic materials that can affect the polarization film, and organic materials that can adsorb onto the parts to interfere with proper adhesion.

Metallic ions affect the bath operation in two ways: they may deposit by immersion on the anode materials when the current is not flowing. In general, if a metal codeposits with the plated metal and is insoluble in the matrix so that no alloy is formed, it beneficially acts as a brightening agent. If, however, an alloy is formed, it acts as an impurity and produces undesirable characteristics in the deposit, including roughness and/or loss of brightness. The effect therefore may depend on the concentration of the extraneous ions and the current density, i.e., the effect is a function of the mole percentage of the foreign metal in the deposit. An extraneous metal ion may act as a brightener at one concentration level and current density, and as an impurity under some other set of conditions. Such is the case, for example, with cadmium or zinc in a nickel solution. Cadmium at levels up to approximately 4 mg/L acts as a brightener for current densities of ca. 0.5 – 3.0 A/dm^2. Above that level, however, it acts as an impurity and produces dark deposits in the low current-density areas. For zinc, the allowable limit is ca. 6 – 8 mg/L and the upper limit ca. 10 mg/L. Even when functioning as a brightening agent, such codeposited metals may affect other characteristics of the deposit, such as brittleness, hardness, stress, etc.

Brighteners at lower concentrations	Cd (ca. 4 mg/L) or Zn (ca. 8 mg/L) in nickel solutions	Impurities at higher concentrations

When an extraneous metal deposits on the anode during idle periods, it may subsequently deplate from the anode as solid particles that remain suspended in the bath, migrate to the cathode, and deposit as discrete particles, which cause roughness. Such is the case, for example, with lead used as a brightener in bronze plating solutions, particularly at high levels.

Metallic contamination may often be removed by electrolytic purification. Cathodes of sheet metal or scrap parts are plated at low current densities, usually ca. 0.5 A/dm^2. At properly selected current densities, the contaminating metal is preferentially removed from the solution. The process is often referred to as *dummying.*

Organic Materials. Many organic materials can interfere with the polarization film causing loss of brightness, streaking, and hazing of the deposit. Often breakdown products of organic systems produced as a result of oxidation at the anode, incomplete reduction at the cathode, or polymerization can act in this way. Typical is the deterioration of some of the aldehydes often used as brighteners in cyanide zinc plating solutions. At high sodium hydroxide levels and temperatures above 50 °C they may undergo the Cannizzaro reaction, polymerizing to long-chain materials. There is not only a selective loss of brightener ingredients, leading to an imbalance in brightener concentrations, but the long-chain materials interfere with the proper development of the polarization film, producing dullness and sometimes streaking or darkening of the deposit.

Organic materials that can adsorb and interfere with adhesion include oil dragged into the solution by improperly cleaned parts, drippage from overly lubricated equipment or introduced by improperly filtered agitation air; buffing compound from incompletely cleaned parts or airborne from nearby buffing operations; wetting agents and cleaner components from incompletely rinsed parts; and many other similar materials. These can cause pitting, roughness, hazing, and loss of adhesion. Silicones are especially damaging.

4.4. Inspection

While there is an increasing tendency for purchasers of plated coatings to specify the characteristics in some detail, especially minimum thicknesses, there are many characteristics of the plated coating that cannot be determined by physical testing. In particular, appearance and the presence of defects such as blisters, pitting, roughness, etc., are best determined visually. The rack plating process especially lends itself to rapid visual inspection since the parts can often be inspected as they are removed from the racks at the end of the process. Even with barrel plated parts a "grab" sample, taken as the parts are being emptied from the barrel, represents a random sample that can be quickly inspected to determine the general quality of the barrel load.

The areas where visual inspection is carried out must be properly lighted. A diffuse white light is most effective, and since many defects can be obscured by reflected light, the ideal inspection station has an inspection box lined with dull white surfaces and with the diffused inspection light coming from overhead. Determining coverage of chrome over nickel, stains on brass and copper, and the inspection of silver-plated items are especially demanding in this regard.

Inspection is a service that enables the production group to operate more efficiently. Fast transfer of information between the inspectors and the production staff is essential. Ideally, the inspectors should be located so that they can detect deteriorating quality early enough, and report it to the production staff promptly enough, that the process can be corrected before any appreciable number of rejects are produced. This implies as well that the inspectors should have thorough training, not only in the quality that is or is not acceptable, but also in the finer distinctions that signal that the process is becoming quality defective.

Where precious metals are barrel plated, statistical control of the plating thickness can assure meeting the specification without applying excessive thicknesses, thus becoming a potent economy tool. However, to be effective the testing facility must be located close to the plating facility so that a random sample can be taken from the barrel and tested promptly before the barrel is removed from the plating tank. In this way, no load ever has to be reloaded and reprocessed because of inadequate thickness.

5. Substrate Preparation

5.1. The Nature of the Adhesive Bond

Adhesion is a micro phenomenon, but since all tests for adhesion are essentially macro tests, the result can present at best an average of the degree of adhesion on the surface. In one sense, adhesion is an absolute: it either exists, or it does not. But since adhesion occurs at discrete points on the surface and adjacent points may have it or lack it, the test procedures actually measure the adhesion that results from the percentage of points properly activated.

There are three different forms of adhesive bonding for plated coatings. If the surface is suitably cleaned and activated, the incoming metallic atoms can crystallize as part of the lattice of the substrate and *chemical bonding* actually takes place. Because the incoming atoms in general have different radii than the substrate, and prefer a lattice of somewhat different dimensions, the boundary layer is somewhat distorted and therefore stressed. However, the adhesion of the two metals will be greater than the cohesion of the weaker metal: if the bond is later ruptured by an exterior force, the rupture occurs within the crystal lattice of the weaker of the two metals.

If the surface is prepared to a lesser degree, the incoming atoms attach themselves to the surface by an *undirected homopolar bonding,* sometimes referred to as London forces and somewhat similar to the cohesive bonding that occurs between the molecules of a liquid. No interchange of electrons take places, although the contact is sufficiently intimate that diffusion of one metal into and through the other may occur. The bond strength of this type of bond is somewhat less then the strength of the first type, but still is such that in the event of rupture the failure usually occurs within the weaker metal.

The third type of bonding is *mechanical bonding,* which occurs as a result of the incoming metal atoms depositing within the interstices of a roughened surface, forming an interlocking bond between the substrate and the deposited metal. Such a bond is obtained, for example,

on a sandblasted or abraded surface and, unless supplemented by one of the other types of bonding, is the weakest bond. It may, however, be adequate for many practical applications. Further, since such roughening produces a considerable increase in the surface area for bonding, there is always an apparent improvement in bond strength when such roughening is used.

For any of these bonds to form, the substrate must be properly wetted by the solution used for deposition so that the surface is in intimate contact with the source of metal atoms.

5.2. The Part Preparation Cycle

Platers often discuss the concept that parts must be *chemically clean* to accept an adherent deposit involving one of the three bonding mechanisms. Yet the environment in which we exist precludes such cleanliness. A truly chemically clean surface can be obtained only in a vacuum. There is, however, an acceptable level of cleanliness even under normal conditions. The preplating or part preparation cycle has as its objective the development of a surface with this acceptable level of cleanliness and activation.

The preparation procedure should not be viewed as a series of discrete steps. Each step of the process is dependent on what went before and in turn affects each step that follows. There are four steps to the preparation cycle:

1) *Gross cleaning,* the removal of the major portion of the surface soils. Gross cleaning may be accomplished by washing with a solvent; degreasing using chlorinated hydrocarbons; cleaning using emulsifiable solvents, either by soaking followed by rinsing, or by using the emulsified solvent as the cleaner; detergent cleaning; or alkaline cleaning. The aqueous materials may be used either by soaking in a tank, with or without agitation; washing in an agitated power washer; or by power spray washing.
2) *Fine cleaning,* the removal of the residues from the gross cleaning step along with adherent or electrostatically attracted solid particles, both conductive and nonconductive. Some fine particles of metal may be sufficiently attracted to the surface to adhere after this step and must be removed in a later step. This fine cleaning is usually carried out electrolytically in an alkaline cleaner. If the part is made the cathode so that hydrogen is evolved, it is referred to as *direct cleaning*; if the anode, as *reverse cleaning.* For many years, it was thought that the scrubbing action of the released gas was the main cleaning action, and direct cleaning was preferred over reverse cleaning since the volume of hydrogen released is double that of oxygen. Aside from the fact that the release of such copious amounts of hydrogen could cause serious hydrogen embrittlement, the electrolytic cleaning process is now recognized as being more complicated, involving changes in the surface oxides and the neutralization of charged colloidal particles prior to releasing them from the surface. Reverse cleaning is therefore generally used, except for lead and silver substrates.
3) *Oxide removal,* the removal of all surface oxides, both natural and those developed in the alkaline cleaning steps. The top few atomic layers of the surface may be severely distorted and stressed by the forming, machining, polishing, and buffing operations used to develop the desired surface. Adhesion of the subsequent coatings is better if these layers are removed. By proper selection of the cleaner in the electrocleaning step, these distressed layers can often be converted to oxides, which can be removed in this step. Additionally, there are many powerful detergent alkalies, such as alkaline silicates, which may adhere to the surface that has been cleaned and which must be removed. The oxide removal is usually accomplished in an acid solution, although alkaline descalers using current and occasionally periodic reversal of the current can sometimes be effective. Hydrofluoric acid, or a soluble fluoride salt, is often added to the acid mixture to remove the silicates remaining from the cleaning step or particular alloying elements that may be resistant to other acids. Prepared powdered acid mixtures containing fluorides, accelerators, inhibitors, wetting agents, deflocculants to remove fine particles, and other ingredients are an excellent way to deoxidize many alloys. In some cases, however, they may not have sufficient free acidity to remove spot welding scale and similar oxides and may

have to be supplemented with mineral acids. In other cases, mineral acids alone are effective.

4) *pH adjustment,* prior to entering the plating solution, the parts carry on their surface a film of rinse water that partially mimics the pH of the last solution used. If this pH is sufficiently different from the pH of the plating solution, some of the metal ions in the plating solution may be precipitated on the surface of the part before any plating takes place. This can cause clouding, hazing, and streaking of the plated deposit, or in extreme cases loss of adhesion. Therefore a final dip in a dilute compatible solution of similar pH to the plating solution is recommended. Typical examples are 5 wt % sulfuric acid before nickel plating or a solution of 15 g of sodium cyanide plus 7.5 g of sodium hydroxide per liter before cyanide copper plating.

Each of these steps except pH adjustment must be followed by effective *rinsing.* The rinsing between operations is as important as the operation itself. Inadequate rinsing can result in cross contamination of solutions and the production of rejects.

Drag-out is the amount of liquid carried out of a processing tank by work being transferred. *Drag-in* is the amount of liquid carried into a processing tank by work being transferred from a previous tank. Drag-in is usually unimportant unless (1) the previous solution contains contaminants harmful to the receptor tank or (2) the volume exceeds the drag-out volume and the evaporation from the receptor tank so that receptor tank volume increases. Drag-out must be reduced to reduce material loss, reduce the required rinsing volume, and reduce the load on the waste disposal system. KUSHNER has produced an excellent treatment of the entire subject [6].

Although four steps are outlined, the pretreatment cycle does not necessarily consist of four tanks and the associated rinses. The nature of the soils on the surface may require several different treatments to accomplish each stage of the cycle.

Considerable research has gone into the development of methods for evaluating the degree of cleaning that is obtained. There is an extensive body of literature on the subject, describing the use of fluorescent tracers, radioactive tracers, the atomizer test, the water-break test, and many others [1, bibliography of Chap. 3 F]. The most widely used is the *water-break test.* A surface that is to be plated in an aqueous solution must be completely wetted by a film of water. If parts that are to be plated are examined prior to entry into the plating solution, any breaks in the film of water on the surface indicates an area that is hydrophobic, rather than hydrophilic, and that is therefore improperly prepared. Because some alkalies and wetting agents in the cleaning solutions can sometimes bridge over hydrophobic areas and give a false positive result, the observation is generally carried out after the acid treatment of the parts, or for purposes of investigating trouble, by immersing the part in a weak acid before making the observation.

5.3. Preparation of Specific Substrates

Different substrate metals, because of their reactive characteristics, require somewhat different methods and solutions to carry out the four steps of the preplating cycle.

The concentrations of acids and aqueous ammonia are frequently given as percent by volume (vol %). This is the volume of concentrated solution to be mixed with water to form 100 parts of solution. For example, 20 vol % hydrochloric acid would be 2 L of concentrated hydrochloric acid (ca. 38 wt %, 22° Bé) mixed with enough water to make 10 L of solution (2 gal of acid mixed with water to make 10 gal). The concentrated solutions from which the diluted solutions are made include hydrochloric acid, nitric acid (69 wt %, 42° Bé), phosphoric acid (ca. 85 wt %), sulfuric acid (98 – 100 wt %, $d = 1.84$), and aqueous ammonia (28 – 29 wt % NH_3, 26° Bé). In addition, some solutions are mentioned which are prepared by mixing volume parts of concentrated acid and water.

5.3.1. Steel

The wide variation in steel compositions requires an equivalent variation in the preplating cycles. In general, the soak cleaners are high in alkalinity and have few restrictions on the type of surfactants used. Electrocleaners are also high in alkalinity. For best results, they should contain an appreciable percentage of soluble silicate

to act as an inhibitor and prevent surface attack. The parts are usually made anodic during cleaning, and high current densities are used. Current densities during cleaning of 7.5 – 12.5 A/dm^2 (75 – 125 A/ft^2) are not unusual. The exception is for nitrided, carburized, or very high carbon steel alloys, which may sometimes develop a carbon smut under these conditions. Lower current densities may be required for these sensitive alloys.

Oxide removal can be accomplished in hydrochloric or sulfuric acid, often with fluoride added. Proprietary powdered acids are also available. The acid should be inhibited to prevent excessive attack and the development of a carbon smut. Transfer and rinsing times must be restricted or a *rust bloom* may develop as a result of the action of the residual acid on the highly active surface that results from acid treatment. Many cycles call for treatment in an alkaline descaler or a mixture of sodium cyanide and sodium hydroxide (30 g/L of each) to remove any trace of this rust.

5.3.2. Cast and Malleable Iron

The high concentrations of carbon and silicon in the surface of cast and malleable iron alloys make them especially prone to the formation of smut. Current densities in electrocleaning should be held to 10 A/dm^2 (100 A/ft^2) maximum. Acid treatment times should be as short as possible, and the acid should always contain a fluoride salt to assist in the removal of silicon from the surface. Because the surface carbon has a very low hydrogen overvoltage, complete coverage in some solutions, e.g., cyanide zinc, may be slow or impossible to achieve. A copper, cadmium, or tin strike is often used to alter this surface characteristic and permit more rapid coverage.

5.3.3. Copper and Copper Alloys

Copper generally may be handled in much the same manner as steel with the exception that the acid used for oxide removal is more dilute. Brass and the other copper alloys are more susceptible to attack than copper itself, particularly in the alkaline cleaning step. Cleaners with lower pH are generally employed and may be fortified with complex phosphates or other complexing agents to prevent excessive oxidation. Current densities in electrocleaning range from 4 to 8 A/dm^2 (40 – 80 A/ft^2), and times should be restricted. If surface conditions demand cleaning times > 2 min, it is common practice to use two stage electrocleaning with the initial cleaning cathodic and the final 30 – 60 s anodic to remove any contaminants that may have been plated out on the surface during the cathodic cleaning. Oxide removal may be accomplished in 20 –30 vol % hydrochloric acid or 5 – 15 vol % sulfuric acid. The use of other acids, such as acetic, fluoboric (fluoroboric), or glycolic, may occasionally give better results. Specially formulated powdered acids are also effective.

5.3.4. Zinc

Zinc is an amphoteric metal that is highly reactive. It is therefore susceptible to attack by strong alkalies and even relatively weak acids, and easily acquires immersion deposits. The soak cleaners used to remove oils and buffing compounds should be detergent type, or mild alkalies buffered to a pH range below 10.5. The use of soaps in these cleaners should be avoided because zinc readily forms metallic soaps, which are most difficult to remove in subsequent steps. Rosin-based soaps, despite their effectiveness in removing buffing compounds, are especially prone to forming such metallic soaps. Their use should therefore be avoided if at all possible, or special precautions taken in the succeeding steps to ensure their removal. Moderately strong electrocleaners may be used provided they contain an adequate percentage of silicate to provide inhibition. The acid for the deoxidizing step must be a low-concentration mineral acid, i.e., 0.5 – 2 vol % sulfuric acid, 5 – 10 vol % fluoboric acid, or a proprietary powdered acid that is buffered and contains fluoride. Contamination of any of the preplating solutions with copper can result in the deposition of an invisible, or barely visible, immersion copper deposit, which may cause blistering after plating or upon heating. A copper or brass strike should be used before applying any plated coating other than zinc or cadmium.

5.3.5. Aluminum

Aluminum has many characteristics that are similar to zinc, but is even more reactive. Because of the wide variation in aluminum alloys, it cannot be considered as a single metal, but rather as a group of four or five related metals. The cycles required for proper preparation are therefore varied: the copper alloys are the simplest to process, while those containing magnesium and silicon are the most difficult.

Aluminum is rarely electrocleaned except in European practice, but etched finishes are common and chemical polishing is often used along with or instead of the oxide removal step. The precleaners should be neutral detergent types, buffered low pH type alkalies, or moderate pH alkalies inhibited with silicates. While many so-called nonetch, nonsilicated cleaners are offered, these are not actually nonetch materials, but rather carefully buffered cleaners with very low etch rates. This type of cleaner may be preferred ahead of operations such as chromating, phosphating, and electropolishing. If silicate inhibitors are used, the oxide removal step should contain a fluoride salt. The acid used for oxide removal must contain an oxidizing agent such as nitric acid or an iron(III) salt. Chromate salts may be used in cycles that are not to be followed by plating, but are considered risky in a plating cycle because of the dangers of dragover of chromium(VI) into the plating slutions and the formation of a stable chromate film on the aluminum.

The following are typical formulas for oxide removal acids:

1) Nitric acid (42° Bé) 500 mL
   Water 500 mL
2) Nitric acid 500 mL
   Water 500 mL
   Ammonium bifluoride 120 g
   (NH_4HF_2)
3) Nitric acid 500 mL
   Sulfuric acid (98 wt %) 100 mL
   Water 400 mL
   Ammonium bifluoride 60 – 120 g

Chemical polishing solutions are based on mixtures of nitric and phosphoric acid, sometimes with added acetic acid, and occasionally with accelerators such as copper(II). They are operated at temperatures close to 100 °C with agitation to avoid gas streaking. Control of temperature and water content are critical to successful operation. Two typical formulas are:

Formula 1	
Nitric acid	2.8 – 3.2 wt %
Water	17 – 23 wt %
Phosphoric acid	64 – 70 wt %
Aluminum phosphate (formed by reaction)	$\leq$ 12 wt %
Copper	0.01 – 0.02 wt %
Formula 2	
Phosphoric acid	70 wt %
Nitric acid	2 wt %
Glacial acetic acid	15 wt %
Water	13 wt %

Many other formulas are listed in the literature, including systems based on phosphoric – sulfuric – chromic acids, phosphoric – sulfuric – nitric acids, nitric – fluoride mixtures, and alkaline systems.

The final step in the preparation of aluminum for plating provides a good example of the use of a carefully prepared solution to deposit an adherent and structurally sound deposit of metal by immersion. Zinc, zinc – copper (Alumon D), zinc – copper – nickel (Alumon N), or zinc – copper – nickel – iron (Bondal), or tin may be deposited from zincate or stannate solutions. All solutions contain high amounts of sodium hydroxide and may be either concentrated (500 – 600 g/L) or dilute (120 – 300 g/L). While formulas for these solutions can be found in the literature, the most effective procedures are patented and are available as proprietary mixtures. In any event, the process is sufficiently complex, and control of raw material quality sufficiently important, that it is generally more economical to purchase prepared and quality-controlled mixtures.

Following the application of the metal film, the aluminum is usually given a cyanide copper strike before applying electrodeposits other than those from cyanide solutions. The alloy zincates permit the use of a pyrophosphate copper strike and, depending on the alloy deposited, the direct application of deposits from acid solutions within a limited pH range. The tin film calls for a special bronze strike from a cyanide solution.

Aluminum may also be plated by first anodizing it in phosphoric acid under carefully controlled conditions. Use of this procedure is limited to special applications.

5.3.6. Magnesium

Magnesium [*7439-95-4*] is very similar to aluminum in that it is highly reactive. It forms surface oxide even more readily than aluminum. It therefore requires special procedures in order to obtain adherent coatings. These procedures are quite specific and do not apply to any other metals.

There are two approaches: applying an immersion zinc coating followed by a cyanide copper strike, similar to the procedure used on aluminum; and direct plating with a special autocatalytic nickel deposit. In either case, the desired decorative or engineering coatings are applied over the initial layer.

After cleaning the parts by alkaline soak and electrocleaning as necessary, the magnesium is pickled in one of the two following solutions:

Ferric nitrate pickle	
Chromic acid (CrO_3)	180 g/L
Ferric nitrate ($Fe(NO_3)_3 \cdot 9\,H_2O$)	40 g/L
Potassium fluoride (KF)	3.5 g/L
Temperature	16 – 38 °C
Time	15 – 180 s

At 38 °C this pickle removes metal at the rate of 3 µm/surface/min, i.e., 3 µm of metal per minute is removed from each exposed surface. Where no dimensional change can be tolerated, the use of the chromic acid pickle is recommended.

Chromic acid pickle	
Chromic acid (CrO_3)	180 g/L
Temperature	16 – 93 °C
Time	2 – 10 min

The use of chromic acid pickles may leave chromate films on the surface that reduce the adhesion of the subsequently deposited coating. After rinsing, the parts are activated in the following solution:

Phosphoric acid (H_3PO_4)	20 vol %
Ammonium bifluoride (NH_4HF_2)	105 g/L
Temperature	16 to 38 °C
Time	15 – 120 s

After rinsing, the zinc coating is applied from a pyrophosphate solution:

Zinc sulfate ($ZnSO_4 \cdot H_2O$)	30 g/L
Tetrasodium pyrophosphate ($Na_4P_2O_7$)	120 g/L
Sodium fluoride (NaF)	5 g/L
or lithium fluoride (LiF)	2 g/L
Sodium carbonate (Na_2CO_3)	5 g/L

Because of the low solubility of the tetrasodium pyrophosphate, generally this solution is prepared and used at elevated temperature (70 – 85 °C). The parts are immersed for 3 – 10 min in the 79 – 85 °C solution and agitated mildly. Glass or fiberglass equipment of any kind cannot be used. Careful control is essential for best results. The pH is maintained between 10.2 and 10.4 (glass electrode, 25 °C).

For the magnesium alloys ZK-60, HM-21, HM-31, or HK-31, a double zinc immersion is required. To accomplish this, the pickling, activating, and zincating steps are repeated. Separate solutions for pickling and zincating should be used for the double zinc immersion technique.

A limited number of proprietary zincating solutions similar to the one listed are available.

The parts are then given a copper strike in either of the following:

Bath 1	
Copper cyanide (CuCN)	41 g/L
Potassium cyanide (KCN)	68 g/L
Free potassium cyanide	7.5 g/L
Potassium fluoride	30 g/L
pH	9.6 – 10.4
Temperature	54 – 60 °C
Bath 2	
Copper cyanide (CuCN)	41 g/L
Sodium cyanide (NaCN)	52.5 g/L
Free sodium cyanide	7.5 g/L
Rochelle salt ($KNaC_4H_4O_6 \cdot H_2O$)	45 g/L
pH	9.6 – 10.4
Temperature	54 – 60 °C

The parts are plated ca. 6 min. With either bath, electrical contact should be made quickly, with initial current 5 – 10 A/dm^2, then with a current of 1 – 2.5 A/dm^2. Cathode rod agitation is suggested.

To utilize the direct autocatalytic nickel method, the parts are processed through the pickling step. They are then given a chemical etch in one of the following:

Etch 1, for alloys containing aluminum	
Chromic acid (CrO_3)	120 g/L
Nitric acid, 11 vol %	to make 1 L
Etch 2, for other magnesium alloys	
Chromic acid	60 g/L
Nitric acid, 9 vol %	to make 1 L

Stainless steel tanks or tanks lined with glass, ceramic, vinyl, polyethylene, or other suitably resistant plastic material are suitable. The parts are immersed 20 – 60 s in the room-temperature solution. The parts are rinsed thoroughly and placed immediately in a hydrofluoric acid dip.

For *thorium-containing alloys* (and other alloys where dimensional change is not critical) the parts are immersed 30 – 60 s in a phosphoric acid pickle at 21 – 32 °C. Metal loss is ca. 13 µm/surface. If thorium alloys have critical dimensions, chromic acid pickle is used and followed with an immersion in a strongly alkaline cleaner to remove possible chromate films.

Magnesium parts are treated in 5.5 vol % hydrofluoric acid for 10 min at room temperature. For treating the alloy AZ61A or AZ80A 20 vol % hydrofluoric acid is used. The parts are transferred to the nickel bath immmediately after rinsing. Ammonium bifluoride, 60 – 90 g/L (8 – 12 oz/gal), can often be substituted for hydrofluoric acid, which eliminates the hazard of handling concentrated hydrofluoric acid.

Autocatalytic nickel plating is carried out in the following bath:

Basic nickel carbonate	
($2\,NiCO_3 \cdot 3\,Ni(OH)_2 \cdot 4\,H_2O$)	10 g/L
Hydrofluoric acid, 0.6 vol %	to make 1 L
Citric acid ($C_6H_8O_7$)	5.2 g/L
Ammonium bifluoride (NH_4HF_2)	10 g/L
Sodium hypophosphite ($NaH_2PO_2 \cdot H_2O$)	20 g/L

Ammonium hydroxide (commercial) is diluted 4 parts to 100 parts and is used to raise the pH. Hydrofluoric acid or ammonium bifluoride is used to reduce pH. The preferred pH is 5.5 – 6.3. In this range, the deposition rate is 20 – 25 µm/h. The presence of sulfate ion is harmful to the bath; therefore, sulfuric acid should not be used for pH adjustment. Mild mechanical agitation is used.

The solution is somewhat unstable. The addition of 1 – 2 mL of triethanolamine per liter stabilizes the bath, but reduces the deposition rate by ca. 30 – 40 %.

The parts are immersed in the nickel solution held at 77 – 82 °C with a pH range 4.5 – 6.8 (glass electrode, 25 °C) The bath sould be filtered either periodically or continuously. The use of a plastic, magnetically coupled pump eliminates problems with shaft seals.

If heavy or specialized electroless nickel deposits are to be applied, the parts can be transferred to the specialized bath after a thickness of 5 µm has accumulated.

The parts are rinsed in cold water. For maximum corrosion resistance when the nickel plate is the final deposit, immerse for 10 min in chromic acid (CrO_3, 2.5 g/L) or sodium dichromate ($Na_2Cr_2O_7 \cdot 2\,H_2O$, 120 g/L). Both solutions are operated at 88 – 100 °C. The parts are thoroughly rinsed in cold water and dried. To improve adhesion, they are baked at 200 °C for 1 h. The deposit should remain adherent and free of blisters.

5.3.7. Stainless Steel

Stainless steel is passive because of the natural oxide that rapidly forms on the surface. Various methods of activating the surface to permit application of adherent electrodeposits have been proposed. The use of cathodic treatment in an alkaline descaler containing sodium cyanide is sometimes successful, as is an acid copper strike. The most successful procedure, however, remains the use of the *Woods nickel strike.* This consists of 45 g/L (6 oz/gal) of nickel as nickel chloride in 10 – 12 vol % hydrochloric acid. It is used at room temperature at current densities of 2 – 10 A/dm^2 (20 – 100 A/ft^2) for 30 – 60 s as required to obtain complete coverage. If the subsequent deposit is to be nickel, the parts can be transferred to the plating tank without rinsing. For other deposits, rinsing should be thorough but rapid so that the nickel plate does not passivate (see Section 5.3.8).

Since the anode efficiency is much higher than the cathode efficiency, the nickel concentration tends to increase. The nickel concentration should not be allowed to exceed 75 g/L (10 oz/gal), or else the effectiveness of the strike may be lost. To reduce the nickel concentration, solution is removed and replaced with fresh hydrochloric acid.

The removed solution may be used to adjust the nickel or the chloride content of a standard nickel bath. If the addition is so large as to seriously reduce the pH of the solution, some of the acidity may be neutralized with nickel carbonate before the addition is made.

5.3.8. Nickel

Nickel rapidly forms a thin oxide and passivates. This oxide formation is sufficiently rapid that it can occur during the rinsing cycle. Such passive nickel does not cover properly in chrome plating solutions. Other deposits, particularly gold, do not adhere properly and may peel. Parts that are stored after nickel plating are almost certain to be passive. The surface must therefore be activated before electrodeposition. The severity of the activation depends on the degree of oxidation that has taken place. Wide variations in the degree and speed of passivation during rinsing can occur as a result of variations in the rinsing water, specifically, its chlorine content, degree of aeration, dwell time, temperature, etc. As a result, an activation treatment that is completely effective in one plant may be totally inadequate in another apparently similar plant. The following activation steps may be used alone or in combination:

1) Cathodic treatment in a high current-density alkaline electrocleaner
2) Treatment in strong hydrochloric acid (50 vol % or stronger)
3) Cathodic treatment in dilute sulfuric acid, with or without added fluoride salt, or a properly formulated powdered acid
4) Treatment in 5 – 10 vol % sulfuric acid with an addition of 3 – 5 g/L (0.4 – 0.7 oz/gal) potassium iodide (KI)
   In this case, activation depends on the development of iodine. In a freshly made solution, there is usually enough oxygen dissolved in the water to develop the required initial amount. However, sometimes a trace of chromic acid (CrO_3) or another oxidizer is added to initiate action.
5) Treatment in one of the numerous proprietary activators available from suppliers
6) Use of the Woods nickel strike (see Section 5.3.7), the most certain method

In all cases following activation, careful attention must be paid to rinsing procedures so that the nickel does not repassivate during the rinsing cycle.

5.3.9. Nonmetallic Substrates

The most common nonmetallic substrate plated is plastic, in particular ABS type molding material (acrylonitrile-butadiene-styrene copolymers, → Rubbers, Synthetic). This plastic may be prepared for plating with the following cycle:

1) Condition the surface with a strongly oxidizing "etch" or "conditioner" to deglaze the surface and render it hydrophilic.
2) Sensitize and activate the surface by successive immersion in tin(II) chloride in hydrochloric acid, a rinse, palladium chloride in hydrochloric acid, and a rinse or by successive immersion in a palladium/tin(IV) chloride colloidal sol, a rinse, an acid accelerator, and a rinse. Either system produces on the surface a thin film of palladium, which acts as a catalyst for a subsequent electroless deposit.
3) Apply a thin film of electroless copper or electroless nickel.
4) Plate with whatever deposit is required.

Other plastics, including SAN (styrene-acrylonitrile copolymer), DAP (diallyl phthalate), polycarbonate, polypropylene, polyethylene, and polyimides, may also be plated. The pretreatment cycle varies only in the conditioning treatments used in the first step.

For electroforming, wax or silicone rubber mandrels may sometimes be used. These can be made hydrophilic by treating with a mixture of chromic and sulfuric acid and silvered with a silver reducing solution, or treated as above starting at Step 2. Glass and nonporous ceramics may be handled similarly. Wax may sometimes be plated by brushing the surface with finely powdered graphite or a metal powder to impregnate the surface with a continuous conductive coating and then plating directly. The graphite or metal powder must be completely free of oil or soaps.

Porous materials such as leather (baby shoes), natural objects (starfish, shells, wood, etc.), and some ceramics must first be sealed with several coats of a suitable polymer such as shellac,

polyurethane, or epoxy varnish. They can then be treated as outlined for wax. They can also be brushed with graphite or powdered metal as for wax, provided the conductive material is applied before the final layer of sealer is completely dry.

6. Equipment

6.1. Tanks

Tanks for containing the various solutions must be made out of suitably corrosion resistant materials. *Alkaline cleaner tanks* are generally made from steel and contain bottom drains to permit easy drainage and replacement. Because of problems with bipolar shorts in these tanks, it is becoming increasingly common to place insulating layers between the anodes and the tank wall and on the bottom of the tank. For the same reason, lined tanks are sometimes used. The tank should also be equipped with a dam overflow to permit removal of oil and grease by overflowing the surface of the tank. Use of an exterior grease trap and recycling system to extract these oils and greases from the cleaner offers the benefit of extended cleaner life and reduced levels of hexane-soluble materials in the waste stream, of special importance if the alkaline waste stream is to be discharged to a sewer system. Provision must be made to heat the tank to the proper operating temperature with heating coils or electrical heaters, or, if a recirculating system is used, an external heat exchanger.

Electrocleaner tanks must be provided with anode and cathode rods and suitable electrodes. It is a mistake to use the tank itself as the electrode. Poor current distribution results. For most electrocleaners, steel electrodes are adequate, and if these are perforated, better current distribution is obtained.

Rinse tanks may be made of mild steel following alkaline solutions, although the use of stainless steel or plastic is becoming increasingly common. After acid solutions, the tanks must be of suitably resistant material. A single rinse following a treatment tank is rarely adequate. Double and triple rinsing is more effective. If the tanks are interconnected to flow from one to the other in the opposite direction to the direction of work travel (countercurrent rinsing), the required water flow will be tremendously reduced, with corresponding decreases in waste treatment costs, water costs, and sewer charges. Formulas for calculating the required number of rinses and the economics of using parallel feed or series feed (counterflow) are available. The savings in rinse water by using series feed are ca. 98.6 % for a two tank system and ca. 99.7 % for a three tank system. The rinse tanks should be provided with bottom drains, dam overflows, and provision for agitation. Low pressure air is a convenient and effective method of vigorously agitating the rinse water.

Tanks for the acid solutions must be made of suitably resistant material: plastic-lined steel, stainless steel, formed reinforced plastic, or similar materials. These tanks usually have no drains or overflows.

Tanks for plating solutions may be constructed of plain steel for many alkaline and cyanide solutions. For other solutions they must be constructed of suitably resistant materials or lined with a suitable plastic material. Linings should be certified as acceptable by the supplier of the brightener system, or tested before installation. Many such lining materials contain plasticizers or residual curing materials that may leach into the plating solution, causing organic contamination. Even for approved materials it is good practice to leach a new liner with a dilute solution of approximately the same pH as the plating solution and at the operating temperature of the plating bath for 24 – 48 h before use.

The tank must be equipped with anode bars and supports and a cathode or work bar unless intended for use on an automatic or semiautomatic machine that provides contact for the racks as part of the operating mechanism. Provision must also be made for heating and filtering the solution as specified in the operating instructions. Plating tanks do not usually have bottom drains because of the danger of loss of solution should the drain valve or cap fail.

The plating tanks are generally constructed of heavier gauge materials than other tanks in the line because of the higher specific gravity of the plating solution and the weight of the anodes which must be supported by the anode bars. Tanks over ca. 125 cm (4 ft) in length and over 90 cm (3 ft) deep should be reinforced at the vertical midpoint and at the tank top to prevent bowing of the tank from hydrostatic pressure.

6.2. Power Supply

The d.c. power supplies consist of a controller for the incoming voltage, a step-down transformer, and a rectifying semiconductor array. The total package is commonly referred to as a *rectifier.*

All electrified tanks should be provided with rectifiers of suitable capacity of voltage and amperage. These rectifiers should generally be sized to allow ca. 50 % expansion over the estimated amperage requirement as a safety factor. If at all possible, the rectifiers should be equipped with remote controls so that they can be located in a separate room with a clean, noncorrosive atmosphere. The controls should be located in a convenient area near the production tanks. Alternatively, the rectifiers can be located near the tanks, and clean air ducted to the ventilation intakes. Totally enclosed water-cooled rectifiers are also available. Most three-phase rectifiers have a ripple factor of ca. 5 %, which is satisfactory for most plating solutions. Where a lower ripple factor is required, as with some gold and chrome plating, it may be necessary to filter the output. Tap switch or variable transformer controls are completely satisfactory for most operations where operators are present to make necessary adjustments. At added expense, controls can provide operation at constant voltage, constant current, ramp start, or other desired settings.

6.3. Heating Equipment

Many of the solutions used require heating to a specified operating temperature. The final rinse is usually heated to facilitate drying. Heating may be done with steam, electrical heaters, or in some cases by direct-fired gas heating. For steam heating, coils or flat welded plates, Platecoils, may be used. The coil should be sized to provide a maximum heat-up time of four hours. In calculating the heat input, required consideration must be given to the total volume of the tank, the tonnage of work processed, and the specific heat of the substrate being processed. With the exception of highly concentrated solutions, such as some chemical polishing and electropolishing solutions, sufficient accuracy is obtained by assuming that the specific heat of the solution is the same as water. Automatic temperature controllers are highly desirable. If heaters are located in the tank, they are preferably located along one of the tank walls, well out of the way of anodes and racks. If the heater is located ca. 5 – 10 cm away from the tank wall, 15 – 30 cm above the bottom of the tank, and an equal distance below the surface of the solution, the natural convective chimney produced circulates cold solution from the bottom of the tank up past the heater, producing a rolling action of the solution and a much more even temperature distribution within the tank. For cleaners and similar alkaline solutions, mild steel coils or heating plates are adequate. For corrosive solutions, stainless steel, titanium, lead, or graphite may be used. Also available are plastic heating coils of various types, generally made of Teflon. Corrosion-resistant electrical heaters are also available, including quartz and steel clad with titanium or lead.

6.4. Ventilation

Local health regulations require that many solutions be ventilated, and in many cases specify the air velocity across the surface of the solution to the ventilation slot. Other local restrictions require that certain contaminants be scrubbed from the air stream before it can be released to the atmosphere. Still other regulations may require that certain types of fumes, e.g., cyanide and acid, be removed by separate systems. These regulations determine the type of exhaust and/or scrubbing systems.

Aside from these requirements, good practice requires that for operator comfort, prevention of structural corrosion, and protection of incoming or finished work, certain other tanks should also be ventilated. Any tank that releases steam or even mildly acid fumes should be ventilated.

Under normal conditions, the ventilation system is shut down when production ends. However, it will be some time before all the heated tanks cool sufficiently to stop releasing steam and other vapors into the now more or less sealed atmosphere. Extreme corrosion of structures and stored parts can result. An auxiliary system, e.g., a relatively small exhaust fan located near or in the roof is most valuable in removing these

fumes and preventing damage. This fan should either be left on continuously or interlocked with the main exhaust system so that it comes on when the main system is shut down.

6.5. Filters

Optimum results are obtained from solutions that are kept scrupulously clean. Filtration is therefore recommended for almost all plating baths. The filter should be sized to provide a flow rate that completely filters (turns over) the bath in ca. 30 min. This assures that even when the rate slows because of cake buildup an adequate filtration rate is maintained. The use of the finest-pore filtering media that provides acceptable periods between filter cleaning is suggested. This can be supplemented by the use of a filter aid such as diatomaceous earth, glass or polyester fibers, etc. As with tank linings, these filter aids should be approved, or tested before use, since they can sometimes introduce harmful materials into the plating solution.

6.6. Agitation

Many forms of mechanical agitation have been developed, particularly for plating tanks, including oscillation of the cathode bar by some type of offset cam. Modern bright solutions, however, require much more vigorous agitation than can be obtained in this way, and air is used for this purpose. Sometimes solutions require air agitation that lifts the solution as much as 15 cm above the normal quiescent level of the tank. Because of the possibility of introducing contamination from entrapped oil or other materials, high pressure air should not be used for this purpose. The air should be supplied by a low-pressure blower located where it picks up clean air, and with the intake carefully filtered. Plastic is the preferred material for distribution; the plastic distribution pipes should be located a slight distance off the bottom of the tank so that the rising solution currents produced do not pick up debris from the bottom of the tank and carry it up onto the work, causing roughness. The distribution pipes should be weighted or otherwise held down so that they do not float and tangle with the racks in the tank.

6.7. Water Supply

The water supply must be adequate and must be readily available where needed. Permanent piping through the plating room should have valved outlets at frequent intervals. Tanks that must be dumped and remade at regular intervals, i.e., cleaners and similar solutions, should have high flow filling systems so that excessive time is not lost waiting for the tank to be filled.

If the water is high in iron, chlorides, or hardness, consideration should be given to pretreatment. For makeup to plating solutions, deionization should be considered. Softening may be helpful for at least the final rinses and the rinses ahead of the plating solutions. Untreated water can be used for noncritical rinses.

6.8. Racks

Plating racks must be designed to fit the equipment being used. The working area of the rack should have a vertical length such that, when the rack is fully loaded with parts and immersed in the treatment tanks, the uppermost piece on the rack is 10 – 15 cm below the surface of the solution. The bottom of the lowest piece on the rack should be at least 15 – 30 cm above the bottom of the tank. If air agitation is used, this clearance should be between the bottom of the rack and the distribution system for the air agitation. The width of the work area should allow adequate clearance from the tank walls. On automatic equipment, there is always some movement of the racks during transfer, and the clearance must allow for this motion, or the racks must be attached to the transfer mechanism sufficiently firmly to minimize the motion. On return-type automatic machines, this dimension is particularly critical, since as the racks turn at the end of the machine, they must not catch on the tank anodes. Therefore, the turning radius of the machine becomes a factor in determining the width of the work area.

The main splines of the rack must have sufficient strength to support the work load, and be of sufficient cross section to carry the required current. Although the current carrying capacity of copper is normally given as 160 A/cm^2

(1000 A/in^2), for copper racks coated with an insulating and protective plastisol coating a safer estimate is 120 A/cm^2 (770 A/in^2). To determine the current carrying capacity of other metals, the factors are 0.6 for aluminum, 0.25 for brass, 0.12 for steel, 0.18 for phosphor bronze, 0.023 for stainless steel, and 0.03L for titanium. Because of the relationship of current carrying capacity and weight, it is common practice to make the main portion of the rack out of copper. Construction must be very firm and assure good contact between rack members, so crosspieces are usually riveted and either brazed or soldered with a high-temperature solder.

Rack tips may be designed to provide positive spring contact for holding the parts. If the parts are sufficiently heavy and have a suitable hole for hanging, the rack tips may be formed as a simple loop over which the part can be hung. Since there is considerable movement of the parts as the rack is immersed in the solution, there should be sufficient reverse curve to these loops to prevent the parts from floating off the rack as a result of this movement. In some cases, e.g., silver plating forks and spoons, the parts may be inserted in a loop or slot, the dimensions of which are such that the part is held on the rack by some projection or increase in diameter, width, etc. For this system to function properly, the center of gravity of the part must be below the supporting contact on the rack. To obtain sufficient strength and springiness to properly hold the parts, rack tips are generally made of phosphor bronze or, for added resistance to processing and metal stripping solutions, stainless steel or titanium.

To restrict current loss and wasted metal, racks are usually given a heavy coating of an insulating plastisol with only the tips left exposed. Proper maintenance, handling, and storage of racks is critical since any damage to this coating can result in unwanted plating, corrosion of the main structure of the rack, and cross-contamination of solutions due to entrapment of solutions by the damaged areas.

If the rack tips are allowed to build up with plated metal, defective parts may result from shadowing or thieving of current by the rack tip, additional metal is wasted plating the enlarged tip, and the danger of cross-contamination by solution entrapment increases because the plated metal usually is coarse and porous in structure. Additionally, the plated layer may reduce the flexibility of the tip, causing breakage and loss of productive capacity. Therefore, racks should be stripped on a regular basis to maintain the tips in a clean condition. Damaged or broken tips should be replaced promptly to avoid the loss of productive capacity.

6.9. Waste Disposal

The consideration of waste disposal is a must in designing a modern plating plant. While there may be a few places in the world where unrestricted discharge of plating wastes to streams or sewage systems is still allowed, this situation will not continue. While the design of the system depends on the production capabilities of the plant, on whether the effluent is to be discharged to a sewage system or a stream, and on the local restrictions, the basic procedure for designing the layout is similar. Furthermore, the design of the system and layout should be part of the original design of the facility. Retrofitting an existing plant with a suitable system is almost always more expensive than including it in the original design.

Waste disposal is inextricably interlocked with water supply and demand. If discharge is to a public treatment works, charges are often based on volume of effluent. Even in the absence of such charges, the cost of treatment for a given total quantity of contaminant is higher for low concentrations, since a greater volume must be treated. Water conservation and the determination of the methods of obtaining the lowest possible volume of effluent is therefore an essential part of the design process. The following steps constitute a broad outline of the design process:

1) Determine and become familiar with local restrictions, including planned changes in the requirements and the timetables for implementation.
2) Review the processes planned for installation.
   Determine the expected dragout from each process. Based on this information and the available space, determine the possibility of using reclaim tanks, the number of counterflow rinse tanks that may be used, and the possibility of counterflowing rinses for multiple use, e.g., use of the last counterflowed

rinse from an acid tank as feed for a first counterflowed rinse for a cleaner. From this information determine the lowest flow rates that can be used and calculate the total effluent flow. Determine which effluents must be treated separately, and those that can be safely mixed and treated in combination.

3) Proceed with the preliminary layout of the plating line.
4) Overlay on this preliminary layout the effluent collection troughs or piping, the location of preliminary treatment steps, and any collection sumps or other equipment that must be located in the plating area, then refine these layouts until acceptable.

6.10. Site Location

The site must be chosen on the basis of:

1) Convenience to other manufacturing operations.
2) Availability of services including power, heating facilities, sewer connections or waste treatment facilities, water supply, and ventilation.
3) Headroom to allow for hoists or automatic equipment and overhead services such as ventilation ducts.
4) Subsurface conditions to permit proper construction of foundations and sumps for waste collection.
5) Location of storage areas.

Since many local building codes require that exhaust stacks must extend a specified distance higher than any building within a specified radius, meeting these restrictions may pose special problems.

6.11. Layout

The layout of the plating facility is of particular importance if operation is to be efficient.

There are two basic layouts: U-shaped, in which the work enters and leaves the plating facility at the same point, and flow-through, in which the work enters at one end of the plating line and leaves at the opposite end. For manually operated lines, the U-shape is generally more efficient provided access to the storage areas is adequate. For automatic or hoist-assisted operation, the choice is in part dependent on the type of equipment. In either case, a complete work flow analysis should be carried out to determine that movement of work and/or operators within the facility does not result in areas of congestion or unnecessary transfer of work from operation to operation.

7. Stripping of Deposits

Plated deposits must be stripped for two reasons: (1) to repair and replate rejects or (2) to maintain the rack contacts in optimum conditions. The cost of stripping and replating a part is roughly four times the original cost of plating plus the cost of the stripping agent used. From the viewpoint of economy, therefore, parts should not be stripped unless one of the following criteria can be met: (1) the cost of stripping and replating is less than the value of the parts, (2) the parts are from a limited production run and the cost of setting up the production equipment to run additional parts is greater than the value of the parts, or (3) there is a critical need for the parts and additional parts cannot be obtained in time to satisfy the need. In most other cases, the parts should be scrapped.

Similar reasoning can be applied to the frequency of stripping for rack contacts. Tips generally do not need to be stripped after each pass through the process. (An exception might be hard chromium plating where very heavy thicknesses are applied.) There is an optimum frequency of stripping based on the rate of buildup of plating on the tips, the thickness at which problems occur, and the cost of stripping. If the parts are being used on full automatic equipment and the stripping process can be incorporated in the process cycle, stripping on each pass is both automatic and economical.

The solutions used for stripping depend on the nature of the plated deposit, the substrate, and whether stripping is done chemically or electrolytically. In general, electrolytic stripping is less expensive, but may require considerable investment in equipment, greater attention, and more time. In evaluating any stripper or stripping method, the ease of waste disposal and/or

recovery of the stripped metals should also be considered.

Immersion in *nitric acid* strips most metals from substrates resistant to the action of nitric acid, such as stainless steel, titanium, and aluminum. Nitric acid (42 °Bé) diluted with water (1 part water and 1 or 3 parts acid) is commonly used, particularly for stripping racks. Proprietary additives are available that increase the rate of stripping by 35 – 50 times.

Organic oxidizing agents such as sodium metanitrobenzoate or sodium metanitrobenzenesulfonate, which are called *nitroaromatics,* may be used with various solubilizing agents such as sodium cyanide or sulfuric acid to strip many metals from various substrates.

There are numerous electrolytic strippers, which often are specific in their action, either as to the metal stripped or the substrates not attacked. Some of the more effective are proprietary. There are also immersion strippers that are specific to particular metals and substrates.

In the past, stripping has not been considered an essential part of the plating operation. Stripping facilities therefore have often been makeshift, poorly designed, and poorly located. It should be recognized that stripping, either for maintenance of racks and other equipment or for reclaiming of rejects, is an essential part of the operation. The design, location, and installation should be given the same engineering attention as in planning a new plating line.

The methods for stripping specific deposits are given at the ends of the chapters describing the specific deposits and plating solutions.

8. Specific Deposits and Plating Solutions

8.1. Aluminum Deposits

Aluminum [*7429-90-5*] cannot be deposited from aqueous solutions because the deposition potential for aluminum is higher than the deposition potential for hydrogen. It can, however, be deposited from solutions of aluminum salts in organic solvents. Special equipment must be used because of the flammability of the solvents and the need to completely exclude even trace amounts of water from the system. While the process has had some degree of success, and while some equipment has been developed to permit continuous operation, it is still experimental. As a result, its applications are rather limited.

8.2. Antimony and Arsenic Deposits

Numerous baths for both antimony [*7440-36-0*] and arsenic [*7440-38-2*] have been listed in the literature. None is completely satisfactory and in the case of antimony the metal may sometimes be deposited in the explosive form. Modern usage generally involves cyanide-based baths containing arsenic or mixtures of arsenic, antimony, and other modifying metals such as copper to produce *antique finishes,* particularly on brass and copper. The most effective of these solutions are marketed as proprietaries.

An arsenic bath based on cyanide and caustic soda was formerly used to produce an antique pewter finish. Toxicity and waste disposal considerations have resulted in the bath being discontinued in most cases, and most handbooks no longer list the formula for the bath. The same considerations have forced the withdrawal or reformulation of many of the proprietary solutions as well.

8.3. Cadmium Deposits

Cadmium [*7440-43-9*] has been used to protect steel from corrosion because of its appearance, apparent greater resistance to marine atmospheres, the fact that the volume of the corrosion salts is less than that of zinc, and in some cases because its low coefficient of friction allows tightening fasteners with torquing equipment without overstressing the fastener. Cadmium is, however, highly toxic and has therefore come under close scrutiny by environmental protection agencies. As a result, its use has declined considerably, and replacements are used except for certain military applications. The most common bath is the cyanide bath:

Cadmium oxide	30 g/L (4.0 oz/gal)
Sodium cyanide	100 g/L (13.1 oz/gal)
or	
Cadmium cyanide	40 g/L (5.1 oz/gal)
Sodium cyanide	75 g/L (10.1 oz/gal)
Sodium hydroxide	20 g/L (2.5 oz/gal)
Control	
Cadmium metal	26.5 g/L (3.5 oz/gal)
Total cyanide (as NaCN)	100 g/L (13.1 oz/gal)
Ratio total NaCN : Cd	3.75 : 1
Temperature	20 – 35 °C
Cathode C.D.	0.5 – 5.0 A/dm^2 (5 – 50 A/ft^2)
Anode : cathode ratio	2 : 1
Efficiency	90 – 95 %

Despite its relatively high efficiency, cadmium plating has been proven to be the source of hydrogen embrittlement in susceptible steels. To overcome this, solutions containing sodium nitrate have been used with mixed success. However, baking before and after plating remains the best and safest procedure for eliminating failures due to hydrogen.

Cadmium cyanide solutions are deleteriously affected by both metallic and organic contamination. Copper and zinc not only affect appearance, but also reduce corrosion resistance. Tin produces a haze at a current density of ca. 1.5 A/dm^2. Metallic contamination may be removed by dummying at ca. 0.5 A/dm^2 for zinc, copper, and lead and at 1.5 A/dm^2 for tin. Temporary correction may be obtained by adding sodium or potassium polysulfide. Treatment with cadmium dust (toxic, avoid inhalation) followed by filtration also removes metallic contamination. Organic contamination may be removed by treatment with activated carbon. For some military applications, in an effort to reduce the possibility of embrittlement to even safer levels, an acid fluoborate solution is sometimes used:

Cadmium fluoborate	240 g/L (32.2 oz/gal)
Fluoboric acid	to proper pH
Boric acid	22.5 g/L (3.0 oz/gal)
Ammonium fluoborate	60.0 g/L (8.0 oz/gal)
Control	
Cadmium	95.0 g/L (12.6 oz/gal)
pH, colorimetric	3.0 – 3.5
Temperature	10 – 38 °C
Cathode C.D.	3 – 6 A/dm^2 (30 – 60 A/ft^2)
Anode : cathode ratio	2 : 1

Licorice (1.0 g/L, 0.134 oz/gal) may be used as a grain refiner, or proprietary brighteners may be added.

Cadmium may be stripped by immersion using nitric acid, a nitroaromatic with cyanide, 50 vol % hydrochloric acid (inhibited), or ammonium nitrate at a concentration of 120 g/L (16 oz/gal). Reverse current electrolytic strippers may also be used.

8.4. Chromium Deposits

There are two main uses for the deposits of chromium [*7440-47-3*]: *decorative chromium,* which is normally restricted to very thin deposits, and *hard chromium,* which is applied at much greater thicknesses. The essential differences between the two deposits are the thicknesses and the conditions of operation. Hard chromium is most often applied at a slightly higher temperature than decorative layers and is not as bright. Many shops alternately use the same solutions for both purposes merely by adjusting the temperature and the current densities.

Chromium is mainly deposited from baths that contain chromic acid (chromic anhydride, $Cr^{VI}O_3$) and a catalyst. The original catalyst was sulfate ion (SO_4^{2-}) provided by sulfuric acid and was added to the bath in amounts that would produce a ratio of 75 : 1 to 125 : 1 (CrO_3/SO_4^{2-}). There are two general classes of solution, those that operate at ca. 250 g/L (33 oz/gal) and those operating in the range of 375 g/L (50 oz/gal). Other anions can also function as catalysts, particularly fluoride. Many proprietary solutions have been developed based on mixtures of fluoride salts and sulfuric acid. If the fluoride salt has a limited, temperature-dependent solubility, an excess may be added to produce a self-regulating solution. By properly choosing the catalyst mixture and the operating conditions, the porosity and the degree of cracking of the chromium deposit may be controlled. For automotive use, two successive layers of differing deposit structure are sometimes used to prevent concentration of corrosive effects, thereby improving corrosion resistance. Where hard chromium is to be used as a lubricated bearing surface, the crack pattern may be specified.

The bath is operated at a temperature of 32 – 43 °C for plating decorative deposits, and 37 – 65 °C for hard chromium. Cathode cur-

rent density is 10 – 20 A/dm^2 (100 – 200 A/ft^2) for decorative work and 15 – 35 A/dm^2 (150 – 350 A/ft^2) for hard chromium. Some trivalent chromium must always be present, and optimum results are obtained when the Cr(III) concentration is approximately 5 % of the Cr(VI) concentration.

The process is sensitive to chromic acid concentration, catalyst ratio, temperature, and current density. In the past, it was reported that metallic impurities could be tolerated to a level of 20 g/L calculated as the oxides of the contaminants before the bath became unstable and difficult to control. The trivalent chromium must be included in this calculation. More recent reports have indicated that instability occurs at levels as low as 1.5 g/L of contaminant. This is particularly true of baths using mixed catalyst systems that include fluoride. Many anions are deleterious, but chloride ion is particularly harmful. Fortunately, it can be readily removed by dummying at high current density, the Cl^- being oxidized to Cl_2 at the anode and evolved from the solution.

For many years, efforts have been made to develop baths based on Cr(III) to reduce disposal problems and improve the efficiency of the bath. While several such baths were developed, the color of the deposit was somewhat dark and did not favorably compare with the blue-white color of the deposits obtained from Cr(VI) baths. Public acceptance was therefore limited despite the other advantages of the baths. A newer bath produces deposits that closely match the desired color. It has high efficiency, can be replated without stripping, and has much better throwing power than the Cr(VI) baths. It does require anode baskets that surround the anodes with a permeable membrane that prevents the Cr(VI) formed at the anode from migrating into the solution, where it acts as a poison. This bath is available only as a proprietary solution (Envirochrome).

Chromium may be stripped by immersion in 22° Bé hydrochloric acid diluted 1 : 1 with water, in warm 50 vol % sulfuric acid, or a heated solution of sodium hydrogen sulfate. It may also be stripped electrolytically in a solution of sodium hydroxide, or a strongly alkaline electrocleaner. Properly formulated alkaline electrocleaners are to be preferred for heavy deposits since they give somewhat higher stripping rates and greater protection against etching of the substrate due to localized reduction of pH.

8.5. Cobalt Deposits

Methods of electrodepositing cobalt [*7440-48-4*] have been known for over 130 years. Because of the lower cost of nickel, cobalt is not often used except as an alloying agent with nickel, especially in times of nickel shortages. The interest in such solutions has remained high, particularly in the Eastern Bloc countries.

The solutions used for depositing cobalt are essentially similar to those used for nickel. Brightening systems are also similar. Electrodeposited cobalt is somewhat more highly stressed than nickel, but this can be relieved by the proper choice of organic stress-relieving compounds. This choice is more limited in range than for nickel. The variation in cobalt ion concentration is much greater than is the case with nickel.

Chloride bath	
Cobalt chloride ($CoCl_2 \cdot 6\,H_2O$)	90 – 105 g/L
Boric acid	60 g/L
pH	2.5 – 3.5
Temperature	49 – 54 °C
Cathode C.D.	3.0 – 4.0 A/dm^2
Sulfate bath	
Cobalt sulfate ($CoSO_4 \cdot 7\,H_2O$)	330 – 565 g/L
Boric acid	30 – 45 g/L
Cobalt chloride (optional)	45 g/L
Sodium or potassium chloride (optional)	17 – 25 g/L
pH	3.0 – 5.0
Cathode C.D.	2.15 – 5.0 A/dm^2

Cobalt may be stripped by immersion using a nitroaromatic (sodium metanitrobenzenesulfonate) and cyanide, a nitroaromatic and dilute sulfuric acid (copper and copper alloys only), or nitric acid. Electrolytically it may be stripped in strong sulfuric acid, a solution of sodium nitrate at a concentration of 360 g/L (48 oz/gal), or proprietary materials.

8.6. Copper Deposits

Copper [*7440-50-8*] is widely used as an undercoating for various other plated coatings on both metals and plastics, on printed circuit boards for through-hole connection, as a stop off in selective carburizing of steel, in electroforming, for

preparing electrotypes, and as a decorative coating, either in its natural state or chemically colored and selectively buffed to create a wide range of decorator finishes. There are numerous types of copper plating solutions available: cyanide – regular, bright, and high speed; pyrophosphate; acid – sulfuric acid regular and bright; and fluoboric acid.

The *copper cyanide baths* have excellent macro-throwing power and are also often used as strike baths before applying other deposits that might produce immersion coatings. Typical cyanide copper plating formulations are shown in Table 1. The Rochelle salt bath produces a finer, denser crystal structure, which is semi-lustrous and can be partially brightened with proprietary additions. Air agitation may be used.

Generally the high-efficiency sodium and potassium baths require a preliminary strike in the standard or Rochelle salt bath. In the two high-efficiency baths, the use of specific brightener systems may require somewhat different concentrations and/or operating conditions. The deposits from the high-efficiency baths may be made full bright with proprietary additions.

Copper cyanide solutions are among the very few solutions in which the cyanide concentration is controlled as "free" cyanide, i.e., the cyanide in excess of that required to completely complex the copper. This is a highly variable quantity. The method of analysis also affects the results. The concentrations given in Table 1 should be accepted as preliminary values to be adjusted as experience dictates. Once the proper value for the operational conditions and the analytical method has been established, no problems should be encountered until operating conditions or analytical method is altered.

Lead, zinc, cadmium, and arsenic contamination may cause poor deposits, but can be removed by dummying. Chromium(VI) may cause blotchy deposits or peeling, or even stop plating completely. Chromium(VI) should be reduced with sodium hydrosulfite or a similar reducing agent, and the $Cr(OH)_3$ removed by filtration. Organic contamination may cause hazing or pitting, but can be removed by treatment with activated carbon.

High carbonates, >90 g/L (12 oz/gal), can cause porous and/or rough deposits. Carbonates may be removed from sodium baths by selective crystallization at temperatures around 0 °C and from all baths by precipitation with calcium or barium salts (substituting $Ca(OH)_2$ or $Ba(OH)_2$ for NaOH or KOH additions, using $Ba(CN)_2$ in place of NaCN or KCN) followed by filtration, or by the use of special ion-exchange resins.

Copper pyrophosphate bath is used for printed circuits or for bright plating. In a modified form the copper pyrophosphate bath may be used as a copper strike where cyanide cannot be tolerated. The unmodified bath requires a preliminary strike.

Copper pyrophosphate	345 g/L (46 oz/gal)
Potassium hydroxide	18 g/L (2.4 oz/gal)
Ammonia (29 wt %)	1 mL/L (1.24 fl oz/gal)
Analysis	
Copper	22.5 g/L (3.0 oz/gal)
Pyrophosphate	157.5 g/L (21.0 oz/gal)
Ammonia	2.0 g/L (0.25 oz/gal)
Ratio P_2O_5/Cu	7 : 1
Cathode C.D.	1 – 7.5 A/dm^2 (10 – 75 A/ft^2)
Agitation	mechanical or air
Anode : cathode ratio	1 : 1 – 2 : 1

Acid copper plating is used for producing heavy deposits for electroforming, for backup plating of electrotypes, and for applying heavy, bright deposits to plastics, zinc-base die castings, some steel automotive parts, and similar applications. Acid copper has poor macro-throwing power, but when run with the proper brighteners has outstanding micro-throwing power. This gives the bath excellent leveling and defect hiding characteristics. Additionally, although the copper is deposited from the divalent (Cu^{2+}) rather than the monovalent (Cu^{+}) state, and therefore requires twice the number of electrons that cyanide copper does, the low operating voltage results in watt-hour savings, reducing power costs.

The standard formula contains:

Copper sulfate ($CuSO_4 \cdot 5H_2O$)	195 – 250 g/L (26 – 33 oz/gal)
Sulfuric acid	30 – 75 g/L (4 – 10 oz/gal)
Control	
Copper	40 – 50 g/L (5.3 – 6.6 oz/gal)
Sulfuric acid	30 – 75 g/L (4 – 10 oz/gal)
Temperature	21 – 49 °C
Cathode C.D.	2 – 10 A/dm^2 (20 – 100 A/ft^2)

A copper strike must be used for steel and zincbase die castings. It is occasionally required for brass as well. For operation at high current densities, moderate to vigorous agitation is required. Some of the proprietary brightener sys-

Table 1. Typical cyanide copper plating formulations

Component or condition	Baths			
	Standard bath, used as a strike or for thin deposits, 1.25 – 2.5 µm	Rochelle salt bath, used for strikes or thin deposits, 1.25 – 7.5 µm	High-efficiency sodium bath, used for bright or heavy deposits, 0.75 – 50 µm	High-efficiency potassium bath ∗, used for bright or heavy deposits, 0.75 – 50 µm

Anode : cathode ratio	2 : 1	2 : 1	2 : 1	2 : 1
Efficiency	30 %	50 %	100 %	100 %

∗ The more expensive potassium cyanide, carbonate, and hydroxide are used only in the high-efficiency potassium bath.
∗∗ Free cyanide is the cyanide in excess of that required to completely complex the copper.

tems use very vigorous air agitation. Almost all of the bright systems require extremely careful control of the chloride ion concentration. Limits are generally in the range of 60 to 100 ppm, although some systems permit concentrations as high as 180 ppm. In some geographic areas, use of deionized water for bath makeup and replenishment is required.

Copper fluoborate baths are also occasionally used for electroforming and printed circuit manufacture. Copper fluoborate is available as a liquid concentrate. This concentrate is diluted with water to give a copper concentration of 60 – 120 g/L (8 – 16 oz/gal). Fluoboric acid is then added as required to maintain the pH at 0.6 – 1.7. The allowable current densities are somewhat higher than for the sulfuric acid bath.

Copper may be stripped by immersion in nitric acid, a nitroaromatic with sulfuric acid, a nitroaromatic with cyanide, or strong chromic acid solutions containing some sulfate ion. Electrolytically copper may be stripped in sodium cyanide – sodium hydroxide solutions, sodium nitrate solution at 360 g/L (48 oz/gal), and proprietary mixtures.

8.7. Gallium Deposits

There does not appear to be any industrial application of plating gallium [*7440-55-3*]. It has been reported that gallium may be deposited from alkaline solutions prepared by dissolving gallium hydroxide in an excess of sodium hydroxide.

8.8. Germanium Deposits

Germanium [*7440-56-4*] cannot be effectively deposited from aqueous solutions. Nonaqueous solutions and fused salt baths have been reported.

8.9. Gold Deposits

Gold [*7440-57-5*] is deposited for decorative purposes, as a contact material in electronics, and in a few cases as a lining for specialized

Table 2. Gold deposition: standard cyanide baths

Component or condition	Finish	
	Matte	Bright
Gold as the cyanide $KAu(CN)_2 \cdot 2H_2O$	2 – 12 g/L (0.25 – 1.5 oz t/gal)	4 – 16 g/L (0.5 – 2.0 oz t/gal)
Potassium cyanide	15 – 45 g/L (2 – 6 oz/gal)	15 – 90 g/L (2 – 12 oz/gal)
Potassium carbonate	0 – 45 g/L (0 – 6 oz/gal)	0 – 30 g/L (0 – 4 oz/gal)
Potassium phosphate	0 – 6 g/L (0 – 6 oz/gal)	0 – 45 g/L (0 – 6 oz/gal)

Brighteners		0.1 – 10 g/L (0.01 – 1.0 oz/gal)
Temperature	50 – 70 °C	15 – 25 °C
pH	11 – 13	
Cathode current density	0.1 – 0.5 A/dm^2 (1 – 5 A/ft^2)	
Agitation	moderate	rapid
Anodes	platinum, stainless steel, gold	platinum, stainless steel, gold

chemical reactors. Most decorative deposits are plated from the standard cyanide solution (Table 2), and the baths are often modified with alloying elements to produce various color effects. Deposits for electronics are generally plated from the neutral or acid baths, and the physical characteristics of the deposits are carefully controlled. Most of these solutions are proprietary and are supplied as prepared concentrates.

The standard cyanide solutions have good throwing power and retard the deposition of base metals. They therefore tend to hold their color well. For producing colored deposits for jewelry the following additions may be made:

14-Karat gold – copper or nickel up to 25 % of total metal.

Green gold – silver ca. 5 % of total metal with small amounts of arsenic or lead to intensify the green color or a ternary alloy of cadmium –copper – gold

Red gold – copper as required to obtain the desired color

White gold – nickel up to twice the gold content

The neutral and acid gold baths (Table 3) operate in pH ranges where cyanide solutions would normally release poisonous hydrogen cyanide gas. Because of the stability of the gold – cyanide complexes, however, this does not occur. These baths are almost all proprietary baths. The gold is supplied as a prepared salt mixture. The chelates used depend on the brightener system and the supplier of the bath, and are either patented or held as trade secrets. The acid golds produce the purest deposits.

Gold baths are especially sensitive to metallic and organic contamination. In many cases, economical purification methods do not exist. Contaminated solutions must be discarded and reclaimed. Strike solutions are used, therefore, not only to improve adhesion, but also to act as traps for contaminants that might be dragged through from the preplating cycle. All tank-mounted equipment should be either corrosion resistant or coated with corrosion-resistant materials to ensure that no corrosion salts from this equipment enters the tank. If copper anode and cathode bars are used, they are sometimes plated with a heavy coating of nickel or tin – nickel to prevent copper corrosion. Alternatively, stainless steel or titanium bars are sometimes used, but their lower conductivity requires a proportionate increase in size.

Since many of the gold baths are operated with insoluble anodes and gold concentration is replenished with gold salts, there is a buildup of salts, which eventually may interfere with operation. The supplier of the gold concentrates has often worked out procedures for removing these excess salts, and the supplier's recommendations should be followed closely.

Since many metals, silver in particular, diffuse through gold, a barrier layer of nickel is often used. Unless suitable care is exercised to prevent the nickel layer from passivating, the gold layer may fail to adhere. Prudence dictates that an activating step be used between the application of the nickel layer and the deposition of the gold. This may be an immersion in a strong HCl dip followed by rinsing; cathodic treatment in an alkaline cleaner followed by acid neutralization and rinsing; or the use of one of the many proprietary immersion activators available. Since the treatment required depends on the nickel solution used, the rinsing time, and the quality of

the rinse water, no one recommendation can satisfy all conditions. Some experimentation is required to determine the optimum procedure for each particular installation.

Gold may be stripped in several different ways, but the most effective in reclaiming defective parts are proprietary cyanide-based strippers, which do not attack nickel and copper substrates. Racks may be stripped in accelerated nitric acid solutions, which in most cases remove the gold as solid flakes by undercutting. The gold flakes may then be reclaimed from the stripping solution by skimming the floating particles or filtering the stripper. Some of the accelerators dissolve some of the gold, and in these instances the stripping solution should eventually be sent out for reclamation.

8.10. Indium Deposits

Indium [*7440-74-6*] is a soft, malleable, silvery-white metal with a low melting point (156 °C). It readily forms diffusion coatings with copper, cadmium, zinc, silver, lead, tin, and gold. The main application is as a coating on bearings to impart corrosion resistance. When used for bearing surfaces, the indium is often diffused into the substrate by heat treatment after plating. In electronic applications, indium is used as a low-pressure bonding material to join copper parts, and for low-temperature soldering as well as for corrosion proofing. Many codeposited alloys exist and are used for various specialized purposes.

The various baths differ slightly in deposit properties and operating characteristics. They may be used interchangeably, depending on the operator's preference.

Sulfate bath	
Indium sulfate ($In_2(SO_4)_3$)	45 g/L (6 oz/gal)
Sodium sulfate	9.75 g/L (1.3 oz/gal)
Control	
Indium	20.0 g/L (2.7 oz/gal)
pH, colorimetric	2.0 – 2.7
Temperature	21 – 60 °C
Cathode C.D.	0.5 – 5.0 A/dm^2 (5 – 50 A/ft^2)
Anodes	indium and platinum
Chloride bath	
Indium chloride ($InCl_3$)	58.0 g/L (7.7 oz/gal)
Potassium cyanide	158.0 g/L (21.0 oz/gal
Potassium hydroxide	40.0 g/L (5.3 oz/gal)
Dextrose	30.0 g/L (4.0 oz/gal)
Control	
Indium	30.0 g/L (4.0 oz/gal)
Total cyanide	140.0 g/L (18.7 oz/gal)
pH, colorimetric	> 13.0
Temperature	21 °C
Cathode C.D	1.5 – 3.0 A/dm^2 (15 – 30 A/ft^2)
Anodes	platinum, steel, stainless steel, graphite
Fluoborate bath	
Indium fluoborate	109.0 g/L (14.5 oz/gal)
Ammonium fluoborate	50.0 g/L (6.7 oz/gal)
Fluoboric acid	15.0 g/L (2.0 oz/gal)
Boric acid	26.0 g/L (3.4 oz/gal)
Control	
Indium	33.0 g/L (4.4 oz/gal)
pH, colorimetric	1.5 – 2.0
Temperature	21 °C
Cathode C.D.	0.5 – 2.5 A/dm^2 (5 – 25 A/ft^2)
Anodes	indium and platinum or graphite

To prevent excessive increase of indium concentration, some of the anode area should be insoluble.

8.11. Iron Deposits

The plating of iron [*7439-89-6*] is mainly used for salvaging worn parts and for specialized electroforming. It has the advantage that after deposition the composition can be altered by carburizing or nitriding to match the combination of ductility and surface hardness obtainable with steel. Some small-scale applications, e.g., the coating of soldering iron tips, also exist. While the properties and low cost of iron are attractive, the corrosiveness of the solutions increases the capital cost of the equipment so that other materials often become economically more attractive.

Even when operated at high temperature, the chloride bath produces the most highly stressed deposits. It is preferred for repair of worn bearing surfaces because of the stress-induced hardness and better wear resistance. The fluoborate bath produces the least-stressed deposits and therefore is often preferred for electroforming. The sulfate – chloride bath is a general purpose bath.

Sulfate – chloride bath	
Iron(II) sulfate ($FeSO_4 \cdot 7H_2O$)	248 g/L (33 oz/gal)
Iron(II) chloride ($FeCl_2 \cdot 4H_2O$)	30 g/L (4 oz/gal)
Ammonium chloride	22.5 g/L (3 oz/gal)
Control	
Iron	58.0 g/L (7.7 oz/gal)
pH, colorimetric	4.5 – 6.0
Temperature	38 °C
Cathode C.D.	5.0 – 10.0 A/dm^2 (50 – 100 A/ft^2)
Agitation	cathode rod and solution
Efficiency	95 – 100 %
Anodes	low carbon steel, bagged
Chloride bath	
Iron(II) chloride	300 g/L (40 oz/gal)
Calcium chloride ($CaCl_2$)	338 g/L (45 oz/gal)
Control	
Iron	84.0 g/L (11.2 oz/gal)
pH, colorimetric	1.0 – 1.5
Temperature	90 °C
Cathode C.D.	6.0 A/dm^2 (60 A/ft^2)
Other conditions are the same as for the sulfate – chloride bath.	
Fluoborate bath	
Iron(II) fluoborate	225.0 g/L (30.0 oz/gal)
Sodium chloride	10.0 g/L (1.3 oz/gal)
Boric acid	22.5 g/L (3.0 oz/gal)
Control	
Iron	55.5 g/L (7.4 oz/gal)
pH, colorimetric	3.0 – 3.7
Temperature	55 – 90 °C
Cathode C.D.	2.0 – 9.0 A/dm^2 (20 – 90 A/ft^2)
Other conditions are the same as for the sulfate – chloride bath.	

The presence of Fe(III) causes brittleness, pitting, and low efficiency. Except in the chloride bath, where high temperatures improve the appearance and ductility of the deposit, excessive temperatures should be avoided since they promote the oxidation of the Fe(II) to Fe(III). The development of Fe(III) may be inhibited by maintaining the solution in contact with iron chips, steel wool, or other forms of metallic iron. Iron(III) may be removed by passing the solution over such a source of metallic iron, by low-current-density dummying, or by raising the pH of the solution to precipitate the Fe(III) as $Fe(OH)_3$ and filtering. Iron baths are similar to nickel baths in that organic contamination can cause stress, pitting, and brittleness. Activated carbon treatment can be used to remove this contamination; however, hydrogen peroxide or permanganate treatment should not be used.

8.12. Lead Deposits

Lead deposits are used for their corrosion resistance and as bearing material. When used on bearing surfaces, lead [*7439-92-1*] is frequently deposited as an alloy (see Section 9.4) or subsequently coated with another material and subjected to heat treatment to produce a diffused surface.

The literature includes references to the deposition of lead from a wide variety of solutions, including nitrate, citrate – chloride, acetate, fluosilicate, fluoborate, perchlorate, oxalate, and many other acid solutions, as well as alkaline solutions. The fluoborate bath is most commonly used.

Lead fluoborate ($Pb(BF_4)_2$)	200 – 470 g/L (27 – 67.5 oz/gal)
Fluoboric acid	20 – 45 g/L (2.6 – 6.0 oz/gal)
Boric acid	20 – 45 g/L (2.6 – 6.0 oz/gal)
Control	
Lead	113 – 255 g/L (15 – 34 oz/gal)
pH, colorimetric	< 1.5
Temperature	25 – 70 °C
Cathode C.D.	0.5 – 60 A/dm^2 (5 – 600 A/ft^2)
Efficiency	100 %
Anode : cathode ratio	2 : 1 or 1 : 1

To improve the quality of the deposit, gelatin or glue may be used at concentrations of 0.15 – 0.38 g/L (0.02 – 0.05 oz/gal), or hydroquinone at 10 g/L (1.3 oz/gal). If the concentration of the colloidal additives is not in the proper range, the deposit may be treed, crystalline, or powdery. Organic contamination can be prevented by activated carbon treatment on a continuous or periodic basis.

8.13. Manganese Deposits

There appears to be no commercial applications for electrodeposited manganese [*7439-96-5*]. Electrowinning of the metal from low-grade ores by electrolysis has been studied, and chloride and sulfate baths for this purpose have been compared. Numerous alloy baths are cited in the literature, but none has reached commercial significance. Deposition of a manganese – nickel alloy has been reported.

8.14. Nickel Deposits

Nickel [*7440-02-0*] is one of the most important, most widely used, and most thoroughly studied of all the electrodeposited metals. Its history goes back over 140 years. It is used as a

Table 3. Gold deposition: the neutral and acid gold baths

Component or condition	Neutral gold baths		Acid gold baths	
	Matte finish	Bright finish	Matte finish	Bright finish
Gold as cyanide *	4 – 16 g/L (0.5 – 2.0 ozt/gal)	2 – 10 g/L (0.25 – 1.0 ozt/gal)	2 – 16 g/L (0.25 – 2.0 ozt/gal)	4 – 12 g/L (0.5 – 1.5 ozt/gal)

* Gold as the cyanide $KAu(CN)_2 \cdot 2H_2O$.

corrosion-resistant undercoating for chromium and gold, as a decorative and corrosion-resistant finish alone, and for numerous engineering purposes. Modern baths are almost all proprietary and deposit the metal in varied forms: bright; semi-bright but with excellent leveling characteristics; and with varied electrochemical activity so that multilayered nickel deposits provide superior corrosion resistance. Baths also exist which deposit extremely hard nickel that can be used as a machineable substitute for hard chromium. Baths that deposit nickel with low internal stress are used for electroforming.

Despite its long history, however, truly high-speed bright plating solutions were not developed until the early 1940s when the brightening effect of saccharin was discovered. Now numerous bright and/or leveling baths are available.

Most of the modern bright baths are based on the Watts type bath:

Watts type bath	
Nickel sulfate ($NiSO_4 \cdot 6H_2O$)	300 g/L (40 oz/gal)
Nickel chloride ($NiCl_2 \cdot 6H_2O$)	45 g/L (6 oz/gal)
Boric acid	30 – 37.5 g/L (4 – 5 oz/gal)
Control	
Nickel	77.0 g/L (10.3 oz/gal)
pH	2.0 – 5.2
Temperature	32 – 71 °C
Cathode C.D.	1 – 6 A/dm^2 (10 – 60 A/ft^2)
Efficiency	95 – 100

The wide range of pH listed is due to the variety of brightener systems available. For any specific system, the preferred operating pH usually lies in a range ca. 0.5 units broad. The brightener system almost always contains a wetting agent to reduce the surface tension of the solution and prevent pitting due to the adherence of gas bubbles to the surface of the parts. Sodium lauryl sulfate is frequently used, but for systems using air agitation nonfoaming types are required. The choice of wetter is extremely important since it can interact with the brightener components and, if incompatible, cause hazing and/or streaking.

Anodes generally are chips, slugs, or electroformed buttons of specially modified nickel contained in titanium anode baskets. The particular type of anode material is often dictated by the brightener system. Anodes should be bagged to prevent roughness.

Agitation varies from the very slight mechanical action obtained by the movement of the parts through the solution by automatic conveying equipment to relatively violent air agitation. For optimum results, continuous filtration is preferred. Since nickel baths are susceptible to organic contamination, either from brightener breakdown or externally introduced, maintenance of a layer of activated carbon on the filter pads is a worthwhile precaution. Even with this treatment, periodic thorough treatment with activated carbon and even hydrogen peroxide or potassium permanganate to completely remove all organics is sometimes required.

In some cases, the all-chloride bath is used to produce bright deposits. It is more often used to deposit a dull, hard nickel, which is used as a replacement for hard chromium in the repair of worn shafts and similar equipment.

All-chloride bath	
Nickel chloride	240 g/L (32 oz/gal)
Boric acid	30 g/L (4 oz/gal)
Control	
Nickel	75 g/L (10 oz/gal)
pH, electrometric	0.9 – 1.1

A wetting agent is used to reduce the surface tension to 35 – 45 mN/m and prevent gas pitting. For some engineering applications where organic additives must be avoided, 5 – 10 ppm of hydrogen peroxide achieves a similar effect. Acceptable cathode current densities are somewhat higher than in the Watts bath. Other conditions are essentially the same.

For electroforming and for building-up worn parts where hardness is not required, the fluoborate or sulfamate bath may be used.

Fluoborate bath	
Nickel fluoborate	320 g/L (29.3 oz/gal)
Boric acid	30 g/L (4.0 oz/gal)
pH, electrometric	3.0 – 4.5
Control	
Nickel	55 g/L (7.3 oz/gal)
Temperature	32 – 71 °C
Cathode C.D.	5 – 10 A/dm^2 (50 – 100 A/ft^2)
Sulfamate bath	
Nickel sulfamate	450 g/L (60 oz/gal)
Boric acid	30 g/L (4 oz/gal)
Control	
Nickel	105 g/L (14 oz/gal)
pH, electrometric	3 – 5
Temperature	49 °C
Cathode C.D	5 – 30 A/dm^2 (50 – 300 A/ft^2)

Other conditions are essentially the same as for the Watts bath. Non-pitter and proprietary stress-controlling agents may be used as required.

Nickel may be stripped in nitric acid if the substrate allows. Organic nitroaromatic strippers with cyanide or sulfuric acid may be used, depending on the substrate. Numerous electrolytic strippers are also available for various substrates.

Black Nickel Deposits. At one time, black nickel, which is a complex alloy of nickel, nickel sulfide, and zinc, was widely used for producing oxidized and relieved finishes on builder's hardware and other items. Since it is a porous, somewhat soft deposit, and has little or no intrinsic corrosion resistance, it is usually applied over a film of nickel, and it must always be protected by some sort of organic film. Its porosity enables it to hold lubricating oil, and it was applied to typewriter parts for this purpose. Development of an immersion process that could be applied over zinc on typewriter parts, and changes in decorator styles, eliminated these major uses, and the plating solution fell into disuse. The current trend toward nonreflective surfaces on automobiles, and possible use as a solar absorber, has rekindled interest in black nickel. For nonreflective surfaces, the underlying nickel must be dull or lustrous rather than bright, or the nonreflective characteristics are difficult to attain.

Baths fall into two general classes, one more concentrated than the other (Table 4). Control of the current density is probably the most important consideration in obtaining good, dull black deposits. Excess current produces gray or even pure nickel deposits. Some operators feel that small amounts of copper in the solution help to darken the deposits even more. Proper activation of the base nickel layer is necessary to ensure adhesion.

Table 4. Black nickel deposition

Component or condition	Dilute bath	Concentrated bath
Nickel ammonium sulfate ($Ni(NH_4)_2(SO_4)_2 \cdot 6H_2O$)	60 g/L (8 oz/gal)	
Nickel sulfate ($NiSO_4 \cdot 6H_2O$)		75 g/L (10 oz/gal)

Agitation	as required	vigorous
Cathode efficiency	80 %	85 %
Anode : cathode ratio	1 : 1	1 : 1

* The rhodium is added as a prepared concentrate.

8.15. Niobium Deposits

There is no commercial method for depositing niobium [*7440-03-1*].

8.16. Rhodium Deposits

Rhodium [*7440-16-6*] is used for thin, bright decorative and tarnish-resistant coatings (0.025 –0.15 µm). Heavier coatings (1.5 – 25 µm) provide high reflectivity, corrosion resistance, and because of its hardness, scratch resistance. Rhodium is used on jewelry, silverware, reflectors, and on electrical contacts. Except when applied over gold or the platinum group metals, an undercoating of nickel is recommended. Rhodium may be plated from either a sulfuric acid or a phosphoric acid bath (Table 5). Platinum anodes should be used. Patented additives are available to eliminate stress in and cracking of deposits. For heavier deposits, a more concentrated solution is used (Table 5).

Rhodium is resistant to the action of most stripping solutions. Light deposits may be removed by undercutting through the cracks in the deposit.

8.17. Silver Deposits

Silver [*7440-22-4*] is used for both decorative and engineering purposes. Decorative uses include silverware, jewelry, lighting fixtures, and other items. Engineering uses include bearings, electronic uses, and special applications such as the plated O-rings used to seal reactors. Many baths have been suggested including nitrate, iodide, thiourea, thiocyanate, sulfamate, and thiosulfate. Only the cyanide bath (Table 6) has received broad industrial acceptance. The main improvements have been in developing brightener systems to give full bright plate directly from the bath to eliminate buffing and in changing the metal and cyanide content to permit high-speed plating for engineering purposes, where thicknesses may be as high as 1500 µm.

Specific brightener combinations may require changes in the concentrations or conditions. With proper brightener additions, conventional and nitrate cyanide baths may be used for deposits up to 2.5 – 33 µm. Filtration is desirable, and mechanical agitation should be used. For the heavy deposit bath, agitation should be vigorous using a combination of mechanical agitation and solution agitation.

Contamination with copper may cause a pink color in the deposit. There is no economic way to remove this contamination. The bath should either be discarded and the silver content reclaimed, or the metal content depleted using stainless steel anodes and then used as a preliminary strike solution.

Table 6. Silver deposition

Component or condition	Baths		
	Conventional bath	Nitrate – cyanide bath	Heavy deposit bath
Silver cyanide	36 g/L (4.8 oz/gal)	22 – 45 g/L (3 – 6 oz/gal)	105 g/L (14.0 oz/gal)

Time	20 s	20 s	20 s	20 s
Anodes	steel	steel	steel	steel

Because silver is a noble metal, the initial deposit must be applied from a strike solution. In many cases, a double strike is used: the first from a mixed copper – silver strike solution and the second from a standard silver strike solution (Table 7).

The copper – silver strike is used as the initial strike on steel. A nickel strike such as the Woods nickel strike (see 5.3.7) may be substituted.

The silver strike is used as the second strike on steel and as the initial strike on other metals. For engineering purposes, three strikes are recommended. The *first strike* is from a Woods nickel strike solution. The *second strike* is plated over the nickel and the *third strike* then applied (Table 7).

Silver may be stripped in nitroaromatic – cyanide strippers where applicable, many of which are now available with inhibitors to protect nickel, and sometimes copper underlayers. It may also be stripped in accelerated nitric acid strippers, which contain 25 vol % nitric acid. Electrolytically, sodium cyanide – sodium hydroxide solutions may be used.

8.18. Tin Deposits

Tin [*7440-31-5*] is soft, ductile, solderable, and resistant to corrosion and tarnish. It is used extensively in electrical and electronic work. Because it is nontoxic, it is widely used to protect items that may come into contact with food. In the presence of oxygen, tin is more noble than steel, and does not offer sacrificial protection. Thin coatings, therefore, being slightly porous, often generate severe pin-hole corrosion in the

steel substrate. However, this condition is easily reversed in the absence of oxygen, and the tin will protect the steel even if slightly porous. Therefore, thin coatings of tin are widely used on steel to be formed into "tin" cans for food. When applied in a thickness adequate to eliminate porosity, or when the coatings are melted (reflowed) after deposition to produce a bright coating and to eliminate porosity, tin offers excellent corrosion protection.

Tin may be deposited from alkaline stannate(IV) solutions or from acid tin(II) solutions. It is widely applied by continuous plating techniques to strip and wire. Baths for this purpose are usually operated under conditions that produce a matte deposit, and the coating is subsequently reflowed.

The sodium and potassium *stannate baths* (Table 8) operate similarly. The potassium bath permits higher operating temperatures, higher current densities, and more leeway in formulation. The potassium salts are more expensive, however. Where there are economies of operation to be gained by higher plating speeds, the added cost of the potassium salts may be justified. For other operations, the sodium bath may be equally satisfactory.

The sodium bath may be used for almost all base metals for applications requiring solderability and protection from corrosion. It may also be used as a strike on cast and malleable iron and steels that are difficult to cover properly. It has excellent throwing power.

Stannous ion, Sn^{2+}, is harmful to the characteristics of the deposit. It is desirable to periodically treat the bath with small amounts of hydrogen peroxide, or to maintain a slight excess of hydrogen peroxide in solution.

Proper treatment of the anodes is essential to efficient operation. The anodes must be filmed with a polarized layer of greenish white tin oxide to assure that the tin dissolves in the stannic form, Sn^{IV}. The anodes should preferably be removed during idle periods and returned to the bath a few at a time on start-up, allowing time for the anodes to film properly before more are added. Alternatively, the bath should be started with a full load of work at very high currents until the anodes film properly. Dummies may be used if necessary to protect the work from excess current during this operation. The bath should never be operated with a high anode-to-cathode ratio since under these conditions the film is lost and tin(II) dissolves into the bath.

The concentrated sodium and the potassium baths are suggested for continuous plating of wire and strip. Anodes of pure tin normally allow anode current densities of 3 – 5 A/dm^2 (30 – 50 A/ft^2). There are also more concentrated potassium solutions, which allow the use of cathode current densities up to 40 A/dm^2 (400 A/ft^2). When these solutions are used, an anode of tin alloyed with 1 % aluminum, which may be operated at 10 A/dm^2 (100 A/ft^2), makes the required anode : cathode ratio more easily attainable.

The potassium baths may also be operated using insoluble steel anodes, thus eliminating the anode problem. A specially prepared tin oxide sol is available which permits control of tin content without generating hydroxide.

For years sodium acetate was thought to be required as a buffering agent, particularly in the sodium bath. However, this is not the case. In any event, acetic acid is the acid of choice for controlling the hydroxide content of the bath.

Tin may be deposited from numerous *acid baths,* but only three are in general use. For continuous tinning of wire and strip, the du Pont Halogen process, stannous fluoborate, and stannous sulfate are the major baths in use.

Halogen bath	
Tin(II) chloride ($SnCl_2 \cdot 2\,H_2O$)	75 g/L (10 oz/gal)
Sodium fluoride	25 g/L (3.35 oz/gal)
Potassium bifluoride	50 g/L 6.7 oz/gal)
Sodium chloride	36 g/L (4.8 oz/gal)
pH	2.7
Addition agents	1 – 2 g/L (0.13 – 0.26 oz/gal)
Temperature	65 °C
Cathode C.D.	45 A/dm^2 (450 A/ft^2)
Fluoborate bath	
Tin(II) fluoborate	200 g/L (26.8 oz/gal)
Fluoboric acid	100 – 200 g/L (13 – 26 oz/gal)
Gelatin	6 g/L (0.8 oz/gal)
β-Naphthol	1 g/L (0.134 oz/gal)
Temperature	20 – 40 °C
Cathode C.D.	2.5 – 42.5 A/dm^2 (25 – 450 A/ft^2)
Stannous sulfate bath	
Tin(II) sulfate	60 – 100 g/L (8 – 13.5 oz/gal)
Sulfuric acid	40 – 70 g/L (5.36 – 9.38 oz/gal)

For strip plating, cresolsulfonic acid 30 – 60 g/L (4 – 6 oz/gal), gelatin 2 g/L (0.26 oz/gal), and β-naphthol 1 g/L (0.134 oz/gal) or

Table 8. Sodium and potassium stannate baths

Component or condition	Sodium bath	Concentrated sodium bath	Potassium bath
Sodium stannate ($Na_2SnO_3 \cdot 3\,H_2O$)	90 g/L (12 oz/gal)	140 g/L (19 oz/gal)	
Potassium stannate			80 g/L (10.6 oz/gal)
Sodium hydroxide	7.5 g/L (1 oz/gal)	15 g/L (2 oz/gal)	
Potassium hydroxide			30 g/L (4.0 oz/gal)
Sodium acetate	15 g/L (2 oz/gal)		
Control			
Tin	38 g/L (5.0 oz/gal)	60 g/L (8 oz/gal)	29 g/L (3.8 oz/gal)
Temperature	60 – 80 °C	93 – 99 °C	85 °C
Cathode current density	1 – 2.5 A/dm^2 (10 – 25 A/ft^2)	4.5 – 6.5 A/dm^2 (45 – 65 A/ft^2)	4.0 A/dm^2 (40 A/ft^2)
Efficiency	60 – 90 %	90 %	80 – 100 %
Anode : cathode ratio	1 : 1	1 : 1	1 : 1

phenolsulfonic acid 40 g/L (5.36 oz/gal), β-naphthol 1 g/L(0.134 oz/gal), and dihydroxydiphenylsulfone 5 g/L (0.67 oz/gal) are also added. Proprietary additives may be used.

For standard rack or barrel plating, proprietary additives, many based on the work of SCHLOTTER and other researchers in Germany and France are used. These brighteners generally require that the chloride content of the bath be held to a maximum of 200 ppm, but when properly operated produce brilliant deposits.

The baths are operated at 15–30 °C. Current densities range from 1 – 4 A/dm^2 (10 – 40 A/ft^2) for mildly agitated baths to 10 A/dm^2 (100 A/ft^2) for highly agitated strip lines.

Tin may be stripped in both acid and alkaline solutions. The stripping can be accomplished by immersion in a nitroaromatic and sodium hydroxide; in an accelerated 25 vol % nitric acid; in a mixture of iron(III) sulfate and sulfuric acid, 100 g/L of each; or in a 120 g/L (16 oz/gal) solution of a mixture of 75 wt % sodium hydroxide, 13 wt % sodium nitrate, and 12 wt % sodium nitrite. Electrolytically, tin can be stripped in dilute sodium hydroxide or in proprietary acid strippers.

8.19. Zinc Deposits

Zinc [*7440-66-6*] has for many years been deposited from the *cyanide bath* (Table 9).

The ratio of total cyanide : zinc should be maintained at ca. 2.75 – 3.25. The higher ratio is used where the most positive throwing power is needed. Higher temperatures cause excessive brightener consumption and eventually lead to organic contamination from brightener breakdown products. Anodes may be a combination of zinc and steel. If all zinc anodes are used, the metal content of the solution tends to increase. The voltage requirement depends on the tank configuration and the plating speed. Mechanical agitation of the cathode is recommended. For best results, the bath should be filtered regularly, if not continuously. Since zinc is reactive and fingerprints easily, a chromate post-treatment is recommended.

Poor throwing power can result from solution imbalance, particularly from a combination of high metal concentration with high caustic or high cyanide. Dark deposits may result from contamination, particularly from copper, cadmium, or lead. Even low levels of copper contamination can cause problems with subsequent chromate treatments and/or loss of corrosion resistance. Hazing of the deposits can result from solution imbalance, organic contamination, high caustic, improper rinsing, or lack of brightener. Polarized anodes may result from low cyanide, low caustic, or insufficient anode area.

Metallic contamination may be removed by low current-density plating (dummying), treatment with sodium polysulfide, or treatment with zinc dust followed by filtering. Organic contamination may be removed by activated carbon treatment.

The standard cyanide bath is a particularly tolerant bath and can be operated under adverse conditions – poor cleaning, oil drag-in, poor housekeeping – and still produce reasonably acceptable visual results. In order to reduce the problems of wastewater treatment and disposal, *low-cyanide zinc baths* (Table 9) have also been developed.

Table 9. Zinc deposition: cyanide baths

Component or condition	Cyanide bath		Low cyanide bath
	Zinc oxide formulation	Zinc cyanide formulation	
Zinc oxide (ZnO)	45 g/L (5.8 oz/gal)		10 – 22 g/L (1.3 – 3.0 oz/gal)
Zinc cyanide ($Zn(CN)_2$)		40 g/L (5.5 oz/gal)	
Sodium cyanide (NaCN)	100 g/L (13.6 oz/gal)	50 g/L (6.6 oz/gal)	2.2 – 19 g/L (0.3 – 2.5 oz/gal)
Sodium hydroxide (NaOH)	50 g/L (7.0 oz/gal)	95 g/L (12.7 oz/gal)	7.5 – 112 g/L (10 – 16 oz/gal)
Analysis or control			
Zinc, as ZnO	45 g/L (4.7 oz/gal)		7.5 – 15 g/L (1 – 2 oz/gal)
Total cyanide	102 g/L (13.6 oz/gal)		2.2 – 19 g/L (0.3 – 2.5 oz/gal)
Total NaOH	95 g/L (12.7 oz/gal)		75 – 112 g/L (10 – 15 oz/gal)
Temperature	20 – 30 °C		20 – 35 °C
pH, colorimetric	> 13.0		>13.0
Cathode current density	1 – 6 A/dm^2 (10 – 60 A/ft^2)		1 – 3.5 A/dm^2 (10 – 35 A/ft^2)
Cathode efficiency	65 – 86 %		65 – 80 %
Anode : cathode ratio	2 : 1		3 : 1
Voltage	1 – 6 V		

The operating conditions are similar to those for the standard cyanide bath, with the exception that this bath is not as tolerant. It is more sensitive to both metallic and organic impurities, as well as shortcomings in surface preparation.

The original brightener systems for zinc cyanide solutions were based on the use of aldehydes with small amounts of metallic ions as brighteners for the low current-density areas. Since aldehydes polymerize in the presence of caustic soda, these brighteners tended to decompose even when the bath was idle, resulting in an excess of metallic components and brightener system imbalance. Operation above the recommended temperature also accelerated brightener decomposition. The aldehyde components of the brightener system were often referred to as temporary brighteners and were added separately to better maintain balance.

Modern systems have replaced the aldehydes with more stable compounds to avoid this problem, but are still sensitive to operation above certain temperature limits.

In a further effort to reduce waste problems, *alkaline noncyanide baths* were developed. These consist essentially of sodium zincate formed from zinc oxide and sodium hydroxide. Complexing agents of various types may also be added. The baths are most often sold as proprietary liquid concentrates. Operating conditions are slightly different for barrel and rack solutions (Table 10).

Table 10. Zinc deposition: alkaline noncyanide baths

Component or condition	Barrel plating	Rack plating
Zinc	8 – 15 g/L (1 – 2 oz/gal)	6 – 12 g/L (0.8 – 1.6 oz/gal)
Sodium hydroxide	80 – 150 g/L (10 – 20 oz/gal)	80 – 120 g/L (8 – 16 oz/gal)
Temperature	18 – 35 °C	18 – 35 °C
Cathode current density	0.5 – 1.2 A/dm^2 (5 – 12 A/ft^2)	1 – 2.5 A/dm^2 (10 – 25 A/ft^2)

These baths are even more sensitive to improper operating conditions than the low cyanide baths.

In recent years, research has been concentrated on the *acid zinc baths.* Major developments in acid chloride zinc baths have produced baths that are not only brilliant but also have leveling action that hides many surface defects. The original work utilized ammonium chloride as an additive to increase conductivity, but these baths were somewhat difficult to control and have for the most part been replaced by baths using potassium chloride (Table 11). High purity anodes are required. Because the bath is highly corrosive, all equipment should be suitably protected.

For plating wire, strip, and other mill products, the acid sulfate bath (Table 11) is often used. Glucose (120 g/L, 16 oz/gal) or licorice (1.0 g/L, 0.33 oz/gal) may be used to refine the grain structure. Steel companies have been reported to have developed proprietary baths that allow current densities up to 10 – 60 A/dm^2

Table 11. Zinc deposition: acid zinc baths

Component or condition	Acid chloride zinc baths				Acid sulfate bath
	With ammonium chloride		With potassium chloride		
	Barrel plating	Rack plating	Barrel plating	Rack plating	
Zinc chloride	34 – 64 g/L (4.5 – 8.5 oz/gal)	74 – 95 g/L (10 – 12.5 oz/gal)	50 – 85 g/L (6.7 – 11.3 oz/gal)	75 – 85 g/L (10.0 – 11.3 oz/gal)	
Zinc sulfate ($ZnSO_4 \cdot 7\,H_2O$)					240 – 360 g/L (32 – 48 oz/gal)
Ammonium chloride	112 – 225 g/L (15 – 30 oz/gal)	90 – 120 g/L (12 – 16 oz/gal)			15 – 30 g/L (2 – 4 oz/gal)
Sodium chloride		45 – 67.5 g/L (6 – 9 oz/gal)			
Potassium chloride			180 – 270 g/L (24 – 36 oz/gal)	202 – 270 g/L (27 – 36 oz/gal)	
Boric acid or	19 – 26 g/L (2.5 – 3.5 oz/gal)	19 – 26 g/L (2.5 – 3.5 oz/gal)	22.5 – 34 g/L (3.0 – 4.5 oz/gal)	22.5 – 34 g/L (3.0 – 4.5 oz/gal)	
Ammonium acetate			7.5 – 12 g/L (1.0 – 1.6 oz/gal)	7.5 – 12 g/L (1.0 – 1.6 oz/gal)	
Aluminum sulfate ($Al_2(SO_4)_3 \cdot 18\,H_2O$)					30 g/L (4 oz/gal) *
Control					
Zinc	16.5 – 30 g/L (2.2 – 4.0 oz/gal)	36 – 45 g/L (4.8 – 6 oz/gal)	24 – 40 g/L (3.2 – 5.4 oz/gal)	35 – 40 g/L (4.8 – 5.4 oz/gal)	55 – 83 g/L (7.3 – 11 oz/gal)
Chloride	93 – 183 g/L (12.4 – 24 oz/gal)	126 – 170 g/L (16.8 – 22.6 oz/gal)	112 – 175 g/L (15 – 23 oz/gal)	135 – 175 g/L (18.0 – 23.0 oz/gal)	
Buffer **	original concentration		original concentration		
pH, colorimetric	4.4 – 5.6				3.5 – 4.2
Temperature	15 – 45 °C				
Cathode current density	0.2 – 6.0 A/dm^2 (5 – 30 A/ft^2)				1 – 3 A/dm^2 (10 – 30 A/ft^2)
Cathode efficiency	close to 100 %				close to 100 %
Anode : cathode ratio	1 : 1				1 : 1

* Sodium acetate may be used in place of the aluminum sulfate at 50 % of this concentration.
** The buffer is boric acid or ammonium acetate.

(100 – 600 A/ft^2) and operation temperatures up to 37 – 65 °C.

9. Specific Alloy Deposits

Solutions for depositing alloy coatings have been extensively investigated, and the deposition of numerous such alloys has been reported in the literature. Only a limited number of these have attained any industrial importance, however.

9.1. Chromium Alloys

There are no known commercial chromium alloy coatings. Chromium – nickel alloys can be deposited from a bath containing chromic acid and nickel sulfate, but this work is still in the research stage. The efficiency of the bath is extremely low, and commercial development does not seem likely.

9.2. Copper Alloys – Brass Plating

Since copper can be plated from both the monovalent and the divalent state, and since the deposition potential can be readily adjusted by the use of complexing agents, numerous copper alloys have been proposed and investigated. These include brass, which is probably the most widely used, an imitation bronze based on cadmium, a true bronze containing tin, and ternary alloys of copper – tin – zinc. They are used for both decorative and engineering purposes.

Brass plating was invented in 1841, but did not come into widespread use until the 1880s. It is used for decorative purposes, where the emphasis is on the color of the deposit, and as a substrate for bonding rubber to steel, where the emphasis is on the color of the deposit composition and crystal structure. For a number of years, there was interest in the use of a white brass, instead of copper, as the initial layer on zinc-base die castings that were to be nickel and chromium plated. Brass solutions are controlled using free cyanide as an analytical criterion.

The color of brass deposits is not completely dependent on composition. Furthermore, the composition of the deposit varies with current density, total metal concentration, free cyanide concentration, the copper : zinc ratio in the solution, temperature, and other operating conditions. The color of the deposits also depends on these conditions. Operation of the original plating solutions to obtain desired results was often more of an art than a science and required extensive experience to produce consistent results. Modern proprietary baths have eliminated many of these problems by use of additives that simplify solution control.

Most brass baths are only 60 – 70 % efficient, but proper control of the operating conditions in specially formulated baths can yield efficiencies up to 90 %. These are the so-called high speed (Hi-speed) baths. Brass anodes are also easily polarized, so anode efficiency is often poor and additions of metal salts to the baths are frequent. For most baths, the anode : cathode ratio should be maintained as high as possible so that anode current densities are low. Additions of Rochelle salt is sometimes helpful, and proprietary baths use a variety of complexing agents, often in combination, to obtain good anode corrosion and efficiency (Table 12).

In all of the brass baths, carbonates in excess of 90 g/L (12 oz/gal) are harmful, and carbonates form particularly rapidly in high-speed operations such as strip plating. Constant removal with a special ion-exchange resin is recommended for control under this conditions. For other operations, periodic removal by freezing or chemical precipitation usually suffices.

A bronze color may be produced by depositing a copper-rich alloy (Table 12, bronze bath). An excellent bronze color may also be produced using a cadmium bronze. A standard copper bath (see Table 1) is modified by adding cadmium cyanide or cadmium oxide dissolved in sodium cyanide until the desired color is obtained. The bath is operated with copper anodes, and the cadmium replenished as a liquid concentrate as required to maintain the color.

A noncyanide brass plating solution has been developed and is being sold as a proprietary solution. It has not made great progress in the market, nor are unbiased reports on its performance available.

Table 12. Brass deposition

Component or condition	Bath 1	Bath 2	Bath 3	Hi-speed bath	Bronze bath	White brass bath
Copper cyanide	27 g/L (3.6 oz/gal)	52.0 g/L (7.0 oz/gal)	42.7 g/L (5.7 oz/gal)	60.0 g/L (8.0 oz/gal)	53.5 g/L (7.2 oz/gal)	15.7 – 20.2 g/L (2.1 – 2.7 oz/gal)
Zinc cyanide	9.0 g/L (1.2 oz/gal)	30.0 g/L (4.0 oz/gal)	18.8 g/L (1.8 oz/gal)	3.75 g/L (05 oz/gal)	3.8 g/L (0.5 oz/gal)	34.4 – 39.7 g/L (4.6 – 5.3 oz/gal)
Sodium cyanide	56.0 g/L (7.5 oz/gal)	90.0 g/L (12.0 oz/gal)	67.7 g/L (9.0 oz/gal)	99.0 g/L (13.2 oz/gal)	62.2 g/L (8.3 oz/gal)	47.7 – 53.6 g/L (6.4 – 7.2 oz/gal)
Sodium carbonate	35.5 g/L (4.5 oz/gal)	30.0 g/L (4.0 oz/gal)	15.0 g/L (2.0 oz/gal)	15.0 g/L (2.0 oz/gal)	30.0 g/L (4.0 oz/gal)	37.5 g/L (5.0 oz/gal)
Sodium hydrogen carbonate		15.0 g/L (2.0 oz/gal)				
Rochelle salt ($NaK(C_4H_4O) \cdot 4H_2O$)		45.0 g/L (6.0 oz/gal)		45.0 g/L (6.0 oz/gal)	45.0 g/L (6.0 oz/gal)	
Sodium hydroxide				60.0 g/L (8.0 oz/gal)		30.0 – 37.5 g/L (4.0 – 5.0 oz/gal)
Ammonium hydroxide	as needed [a]	0.5 – 1.5 vol %	12.5 – 25.0 g/L (1.5 – 3.0 oz/gal)		1.0 – 5.0 g/L (0.1 – 0.7 oz/gal)	
Control						
Copper	20.0 g/L (2.5 oz/gal)	37.5 g/L (5.0 oz/gal)	30.0 g/L (4.0 oz/gal)	42.5 g/L (5.7 oz/gal)	38.0 g/L (5.1 oz/gal)	11.0 – 14.0 g/L (1.5 – 2.0 oz/gal)
Zinc	5.0 g/L (0.65 oz/gal)	15.0 g/L (2.0 oz/gal)	7.7 g/L (1.0 oz/gal)	2.25 g/L (0.3 oz/gal)	2.1 g/L (0.28 oz/gal)	29.0 – 33.5 g/L (4.0 – 5.0 oz/gal)
Cu : Zn ratio	4.0 : 1	2.5 : 1	4.0 : 1	19 : 1	18 : 1	0.38 – 0.44 : 1
Free cyanide	17.5 g/L (2.3 oz/gal)	7.5 g/L (1.0 oz/gal)	7.5 g/L (1.0 oz/gal)	36.0 g/L (4.8 oz/gal)	4.5 g/L (0.6 oz/gal)	4.7 – 6.4 g/L (0.6 – 0.85 oz/gal)
pH	10.3 – 10.7	10.3 – 10.7	9.8 – 10.3	[b]	10.3	[b]
Temperature	28 – 50 °C	43 – 60 °C	35 – 44 °C	60 °C	38 – 60 °C	21 – 29 °C
Cathode current density	0.5 A/dm^2 (5.0 A/ft^2)	0.5 – 3.5 A/dm^2 (5 – 35 A/ft^2)	0.5 – 1.6 A/dm^2 (5 – 16 A/ft^2)	up to 10 A/dm^2 (up to 100 A/ft^2) [c]	0.5 – 3.2 A/dm^2 (5 – 32 A/ft^2)	4.3 A/dm^2 (45 A/ft^2)
Cu : Zn anode ratio	80 : 20	70 : 30	80 : 20		95 : 5	35 – 65

[a] Addition of ammonium hydroxide is used to control the pH.
[b] pH not controlled.
[c] The maximum current density depends on the degree of agitation.

9.3. Gold Alloys

The use of antimony and selenium as hardeners for gold deposits is mentioned in page 10, and the use of copper, nickel, and silver as color modifiers for decorative gold deposits is described in 8.9.

9.4. Lead Alloys

The use of antimony codeposited with lead to strengthen the plated alloy has been reported. Lead – silver alloys and lead – cadmium alloys have also been reported. A ternary alloy of lead – tin – antimony has been suggested. However, the main industrial alloys continue to be the lead – tin alloys, which are used for improved solderability, particularly in electronic work (usually 50 – 70 % tin), for bearing surfaces (6 – 20 % tin, sometimes with small amounts of copper or antimony), and occasionally as a lubricant for some machining operations. The deposit varies with the ratio of the metals in the solution, the total metal content, and the current density. (An increase in current density increases the tin in the deposit.) Additives are required to improve the character of the deposit. The compositon of the anode should be the same as the deposit. A typical bath to produce lead : tin deposits is as follows:

Lead fluoborate	
Tin(II) fluoborate	see Table 13
Boric acid	16.5 g/l (2.2 oz/gal)
Fluoboric acid	30 g/L (4 oz/gal)
Glue	0.4 g/L (0.05 oz/gal)
Control	see Table 13
Boric acid	22.5 g/L (3.0 oz/gal)
Fluoboric acid	30 g/L (4.0 oz/gal)
pH, colorimetric	>0.5
Temperature	21 – 38 °C
Cathode C.D.	2.5 A/dm^2 (25 A/ft^2)
Efficiency	100 %
Anode : cathode ratio	2 : 1

A low concentration of glue causes a granular deposit, loss of throwing power, and decreased tin in the deposit. Proprietary additives may be used in place of the glue. Typical of acid baths, these baths do not have good throwing power and would normally be unsuited for plating through-hole circuit boards. However, increasing the free fluoboric acid and using peptone to replace the glue makes the bath suitable, and proprietary additive systems produce even better results.

9.5. Nickel Alloys

Numerous nickel alloys may be deposited. Cobalt easily codeposits with nickel and has been used both as a modifying alloying element and as a substitute for nickel during times of nickel shortages. Deposition of nickel alloys with tin, copper, cobalt, zinc, and iron from pyrophosphate solutions has been reported, but commercial applications have not developed. Nickel – zinc has been suggested as a coating for sheet steel. This same alloy has been suggested as a replacement for cadmium for corrosion protection of fasteners. A rhodium – nickel alloy bath has been developed. A ternary alloy of cobalt – nickel – copper from a pyrophosphate bath has been reported. The three baths in commercial use are nickel – iron, nickel – tin, and nickel – palladium.

The *nickel – iron bath* was widely promoted as an effective and economical substitute for nickel plating, and numerous baths were installed. Despite many advantages, difficulties with solution control and difficulty in stripping rejects caused an appreciable return to standard nickel baths. Many nickel – iron baths still remain in operation, however.

In addition to the lower cost of iron, and the accompanying economies, nickel – iron deposits offer corrosion protection equivalent to nickel in many applications, and exhibit less tendency to passivate. Coverage in chromium plating solutions is therefore better, and replating of rejects requires less stringent activation procedures. There is also less danger of peeling due to laminated plate should the current be interrupted in the plating cycle. Brightener systems are available to produce excellent leveling and brilliant deposits.

Typical nickel – iron bath	
Nickel sulfate	70 – 75 g/L (9 – 10 oz/gal)
Nickel chloride	70 – 75 g/L (9 – 10 oz/gal)
Iron(II) sulfate	10 – 20 g/L (1.3 – 2.6 oz/gal)
Boric acid	30 – 40 g/L (4.0 – 5.5 oz/gal)
Stabilizer	20 – 30 g/L (2.6 – 4.0 oz/gal)
pH	2.5 – 3.2
Temperature	60 – 65 °C

The stabilizer is required to maintain the iron in its 2+ state; one suggested material is trisodium citrate.

Table 13. Composition of baths to deposit specific lead – tin alloys: lead and tin components

Component	6 % tin	10 % tin	40 % tin	60 % tin
Lead fluoborate	345 g/L (46 oz/gal)	330.0 g/L (44 oz/gal)	217.5 g/L (29 oz/gal)	146.0 g/L (19.5 oz/gal)
Tin(II) fluoborate	30 g/L (4 oz/gal)	50.0 g/L (6.7 oz/gal)	202.5 g/L (27 oz/gal)	300.0 g/L (40 oz/gal)
Control				
Lead	95 g/L (12.6 oz/gal)	91.0 g/L (12.1 oz/gal)	60.0 g/L (8.0 oz/gal)	40.0 g/L (5.4 oz/gal)
Tin	6.0 g/L (0.8 oz/gal)	10.0 g/L (1.3 oz/gal)	40.0 g/L (5.4 oz/gal)	60.0 g/L (8.0 oz/gal)
Pb : Sn ratio	16 : 1	9.3 : 1	1.5 : 1	0.68 : 1

The brightener systems are in many ways similar to the standard systems used in bright nickel solutions. Specific brightener systems may require considerable deviation from the concentrations and conditions listed above. Control and purification procedures are similar to those used for nickel with the exception that hydrogen peroxide or permanganate treatment cannot be used for the removal of organic contamination.

Nickel – iron deposits may be stripped in nitric acid or in specially developed strippers. Problems in stripping high-current-density deposits sometimes occur.

Deposits of *tin – nickel alloys* were obtained in the early 1930s, but the current baths are based on developments from the 1950s. The deposit is almost inert to many reagents and possesses excellent resistance to atmospheric corrosion. It has excellent throwing power and can be soldered. The recommended bath contains:

Tin(II) chloride ($SnCl_2$)	49 g/L (6.5 oz/gal)
Nickel chloride ($NiCl_2 \cdot 6H_2O$)	300 g/L (40 oz/gal)
Ammonium bifluoride	56 g/L (7.5 oz/gal)
Ammonium hydroxide	to adjust pH to 2.0 – 2.5
Temperature	$68 \pm 3\,^{\circ}C$
Cathode C.D.	1 – 3 A/dm^2 (10 – 30 A/ft^2)

Hydrated tin(II) chloride may be used with the appropriate adjustment in concentration. The total fluorine content (initially 37.5 g/L or 5.0 oz/gal) should always be at least as high as the total tin (initially 30.0 g/L or 4 oz/gal). When the alloy is to be applied to steel, an undercoating of copper or bronze greatly improves the corrosion resistance [10], [11]. The main drawback to the coating is the extreme difficulty of stripping it without damaging the substrate.

Nickel – palladium alloys are being seriously considered as substitutes for gold in electronic applications. Varying the metal concentrations in solution yields alloys containing 80 – 90 % palladium. A typical bath contains:

$Pd(NH_3)_2Cl_2$	40 g/L (5.4 oz/gal)
Ammonia	9 vol %
Ammonium sulfate	50 g/L (6.7 oz/gal)
Nickel sulfate	45 g/L (6.0 oz/gal)
Additives	as needed
pH	8.5
Temperature	$30\,^{\circ}C$
Cathode C.D.	1 A/dm^2 (10 A/ft^2)

This bath will produce an alloy 80 wt % Pd.

Composition and concentration control of the additives may be critical to deposit properties particularly for high-speed plating.

9.6. Tin Alloys

Tin alloys with lead, copper, and nickel are discussed under lead, copper, and nickel alloys.

Tin and cadmium can be deposited in all proportions from sodium hydroxide – sodium cyanide baths. Also reported have been baths based on fluoborate, sulfate, and several other anions. The alloy has been used on threaded fasteners, and for some time the corrosion resistance of the alloy was felt to be superior to cadmium in marine environments, but this has been questioned.

A tin – zinc alloy can be plated from a similar solution and was proposed as a substitute for cadmium. It has excellent solderability. The corrosion resistance appeared variable until it was determined that the application of a chromate film by immersion gave the variable results, and an electrolytic chromate film was developed that eliminated this problem. The zinc is sufficiently segregated that the alloy exhibits the potential of zinc and therefore provides the same protection. However, when corrosion does occur, the voluminous corrosion salts associated with the corrosion of zinc do not develop.

A low antimony alloy (as low as 0.2 % Sb) is immune to tin pest, and antimony is therefore included in many baths as a low-level additive. Bismuth behaves similarly, and a process based on tin – bismuth alloy anodes has been commercialized. In view of the usefulness of tin – nickel, tin – cobalt baths were also investigated, but no commercial application has developed. Ternary alloys of tin – copper – zinc have been developed, and at least one bath was promoted commercially. However, it fell into disuse because of difficulties with control. More recently, two proprietary baths with simplified control procedures have been promoted, but applications and use appear to be limited. They were in part intended as replacements for chromium plating, and the development of a successful chromium(III) bath has contributed to the lack of acceptance. Patents exist on baths for plating tin – gold, tin – indium, tin – iron, and tin – silver, but commercial applications have been limited.

9.7. Zinc Alloys and Other Alloys

The zinc alloys with copper, nickel and tin are discussed under copper, nickel, and tin alloys. There is no other zinc alloy of commercial importance.

Numerous other alloys are mentioned in the literature, including gold – silver, gold – tin, silver – cadmium, and many others. Ternary alloys are also frequently mentioned. None of these, however, has experienced any major commercial development.

10. Nonelectrolytic Deposits

Deposits applied by nonelectrolytic methods can be classified into three groups: immersion or displacement deposits, noncatalytic chemically reduced deposits, and catalytic chemically reduced deposits (catalytic electroless plating).

10.1. Immersion Deposits

Immersion deposits form whenever the substrate is more active than the ions in solution. Although these deposits are often nonadherent and of poor physical quality, careful attention to solution composition and operating conditions can produce deposits that are acceptable for certain purposes. The zincate and stannate solutions used in plating aluminum (see 5.3.5) are examples of special cases producing acceptable deposits.

Liquor Finish. A copper – tin alloy deposited on steel wire from a solution of copper sulfate, tin sulfate, and sulfuric acid – liquor finish – is used on wire as a final finish or as a drawing lubricant. Proprietary solutions with modifying agents to improve the deposit are often used.

Copper. Copper from a dilute copper sulfate – sulfuric acid solution is used as a drawing lubricant on steel wire and occasionally on steel sheets that are to be deep drawn. Zinc, and occasionally magnesium phosphate, coatings have to a large extent replaced the use of copper.

Gold. Immersion gold is now rarely used. However, copper and its alloys may be coated in a solution of:

Potassium pyrophosphate	80 g/L (10.7 oz/gal)
Potassium cyanide	0.025 g/L (0.0033 oz/gal)
Gold as gold chloride	2.0 g/L (0.27 oz/gal)
Temperature	65 – 87 °C.

Tin. Tin is probably the most widely used immersion deposit. Pins, screws, buttons, and eyelets are typical. Tin immersion deposits are also used on the inside of brass lipstick cases to prevent discoloration of the lipstick by contact with the copper alloy. Numerous solutions exist. For example:

Solution 1	
Potassium hydrogen tartrate	saturated solution
Tin(II) chloride ($SnCl_2 \cdot H_2O$)	0.75 – 2.5 g/L (0.1 – 0.33 oz/gal)
Solution 2	
Tin(II) chloride ($SnCl_2 \cdot H_2O$)	15 g/L (2 oz/gal)
Sodium hydroxide (NaOH)	19 g/L (2.5 oz/gal)
Sodium cyanide (NaCN)	7.5 g/L (1.0 oz/gal)

Both solutions are operated boiling.

There are also proprietary solutions available with longer life, improved characteristics, and easier waste-disposal procedures.

10.2. Noncatalytic Chemically Reduced Coatings

Noncatalytic chemically reduced coatings have been in use for many years. Their two main drawbacks are that only relatively thin coatings can be deposited and that all surfaces, including the container, receive a coating. While these solutions are sometimes used by immersion, they are now more often applied by spraying the solutions from a dual spray gun system.

Silver. Silver was undoubtedly the first metal to be applied in this manner and was used to produce mirrors and coat nonconductors. One widespread use is for rendering phonographic record masters (lacquer or wax) conductive before electroforming the stampers used in the production of copies.

The original Brashear processes (sugar, Rochelle salt, silver nitrate, ammonia, and formaldehyde) have been abandoned because of the danger of explosive silver fulminate. Modern systems use an excess of ammonia, which avoids this problem. Furthermore, these solutions may be safely stored. The Brashear solutions had to be used immediately or discarded.

In the spray process, most of the silver can be made to deposit on the work by properly directing the spray and adjusting the spray pattern to avoid overspray. This is a much more efficient use of silver than in the immersion process. A typical two-part solution consists of:

Solution number 1	
Silver nitrate ($AgNO_3$)	10 g/L (1.3 oz/gal)
Aqueous ammonia (28 wt %)	4.5 g/L (0.59 fl oz/gal)
Solution number 2	
Hydrazine sulfate	19 g/L (2.56 oz/gal)
Sodium hydroxide	5 g/L (0.64 oz/gal)

An equivalent amount of potassium hydroxide may be substituted for the NaOH. Hydrazine nitrate or hydrate may be substituted in equivalent amounts for the hydrazine sulfate.

The solutions are sprayed in equal volumes from a dual spray gun. The speed of the reaction may be slowed by increasing the NH_3 content or decreasing the NaOH content.

Copper. While not as widely used, copper may be applied in a similar way.

Solution number 1	
Copper sulfate ($CuSO_4 \cdot H_2O$)	35 g/L (4.7 oz/gal)
Sulfuric acid (H_2SO_4)	50 g/L (6.7 oz/gal)
Solution number 2	
Sodium hypophosphite (NaH_2PO_2)	350 g/L (47 oz/gal)

The solutions are sprayed at a ratio of 2 parts of number 1 to 1 part of number 2 at 80 °C.

Gold. Spray solutions for gold have been patented and found some use in the early stages of the U.S. space program. The solutions are delicately balanced, relatively inefficient (ca. 50 % of the gold is wasted), and correspondingly expensive to use. They have not found general application.

10.3. Catalytic Electroless Plating

These systems stem from the work of Brenner and Riddell. The basic reaction requires the presence of a catalytic metal that allows reaction to proceed. This requires that the metal being deposited be itself a catalyst. The advantages of the systems are:

1) Provided there is adequate agitation to maintain fresh undepleted solution in contact with all surfaces at all times, the deposit is uniform over the entire surface even if the shape is highly complex.
2) Deposits are usually less porous than the same metal deposited electrolytically.
3) Racking or fixturing is greatly simplified.
4) Nonconductors may be coated.
5) Deposits often have special chemical or physical properties since the deposit is an alloy of the metal and a compound formed from the reducing agent. For example, with hypophosphite the deposit is an alloy of the metal and the metal phosphide, and with boron reducing agents the metal and the metal boride deposit.

Arsenic. Hypophosphite baths have been developed with rates of 2.5 µm/h or less and recommended thicknesses of 0.5 µm or less. No commercial application has developed.

Chromium. No truly autocatalytic bath has been verified.

Cobalt. Commercial processes are not generally available, but numerous proprietary methods of producing magnetic memory films have been developed. Published data indicates that, unlike nickel, cobalt may only be deposited from alkaline solutions.

A typical formula used mainly for memory disc production consists of:

Cobalt chloride ($CoCl_2 \cdot 10\,H_2O$)	30 g/L (4 oz/gal)
Sodium hypophosphite (NaH_2PO_2)	20 g/L (2.7 oz/gal)
Ammonium chloride (NH_4Cl)	50 g/L (6.7 oz/gal)
Sodium citrate ($Na_3C_6H_5O_7$)	35 g/L (4.7 oz/gal)
pH	9 – 10
Temperature	95 – 100 °C
Deposition rate	15 µm/h

Deposits are dull. Improved physical properties without improvement in appearance may be obtained by decreasing the hypophosphite to 10 g/L (1.3 oz/gal) and increasing the citrate to 100 g/L (13.4 oz/gal), but the rate of deposition falls to 5 µm/h. The efficiency of the bath appears to be about double the efficiency of nickel baths. Many of the additives developed by GUTZHEIT for electroless nickel are also effective in the cobalt baths.

Copper. Commercial applications date from the late 1950s. Major applications have been for through-hole printed circuit boards, the additive process for printed circuit boards, and for plating molded plastic parts.

The formulations are based in a general way on the Fehling test for aldehydes. There is a wide variation in formulas. A typical one would be:

Copper sulfate ($CuSO_4 \cdot 5\,H_2O$)	30 g/L (4.0 oz/gal)
Rochelle salt ($NaK(C_4H_4O_6) \cdot 4\,H_2O$)	135 g/L (18 oz/gal)
Formaldehyde (37 wt %)	150 g/L (20 oz/gal)
Sodium hydroxide (NaOH)	40 g/L (5.4 oz/gal)
Temperature	20 °C

Rate of deposit is up to 25 µm/h. Many different complexing agents may be used. A combination of EDTA and Rochelle salt appears to have a beneficial effect on the rate of deposition. Similarly, many different reducing agents are effective; formaldehyde and paraformaldehyde are preferred. The pH must be constantly adjusted since the progress of the reaction reduces the pH. The bath may be stabilized with very low levels of sulfur compounds, but, as also happens with nickel, slightly higher amounts slow or stop deposition. Cyanide, polysiloxanes, or substituted silanes may be used to improve the ductility of the deposit and improve its appearance.

Gold. There are several patented gold baths. It is however questionable whether they are truly autocatalytic. Useful solution life also appears limited. One bath, verifiably autocatalytic, was developed in the late 1970s. It is covered by patents and available only as a proprietary material.

Iron. Uses for electroless iron plating seem to be limited. Few verifiably effective autocatalytic baths exist. One bath developed by RUSCIOR and CROILA contains:

Ammonium iron(II) sulfate	30 g/L (4 oz/gal)
Sodium citrate	45 g/L (6 oz/gal)
Sodium hypophosphite	30 g/L (4 oz/gal)
pH (adjusted with NaOH)	>9.5
Temperature	60 – 90 °C

The rate is generally low, one figure cited being 2 µm/h. The coating is ferromagnetic.

Nickel. Nickel is by far the most widely used autocatalytic deposit. It has received the widest attention and, because of its commercial importance, has been most thoroughly researched. Much of this research has been carried out by plating solution suppliers, who have developed many highly specialized baths. One survey, conducted in 1984, showed that there were over 44 different proprietary electroless nickel solutions available from suppliers in the United States alone.

Nickel – Phosphorus Alloys. The present baths are generally based on the acid baths developed by BRENNER and RIDDELL.

The reactions are extremely complex, and a number of theories have been advanced to explain the complete mechanism. The most widely accepted theory is the hydride theory. This proposes that the interaction between the hypophosphite and water leads to the formation of a hydride ion, H^-. This hydride ion acts as the reductant for the metal and at the same time produces hydrogen, which is liberated as a gas: in acid solution,

$$H_2PO_2^- + H_2O \longrightarrow HPO_3^{2-} + 2H^+ + H^-$$

in alkaline solution,

$$H_2PO_2^- + 2OH^- \longrightarrow HPO_3^{2-} + H_2O + H^-$$

then,

$$Ni^{2+} + 2H^- \longrightarrow Ni^0 + 2H$$

Because H^- is unstable, only about one-half of the hypophosphite actually reduces nickel. Formulations consist of a source of nickel ions, sodium hypophosphite, buffers, complexing agents, accelerators, stabilizers, and wetting agents. The normal source of nickel ions is either nickel chloride or nickel sulfate. Since the baths are most generally supplied as prepared concentrates, these choices are dictated by the need for high solubility, high purity, ready availability, and moderate cost.

The concentration of hypophosphite in the bath can be critical. Low concentrations yield low rates, which increase as the hypophosphite concentration is increased to an optimum level. As the concentration exceeds the optimum level, the rate again falls off until a concentration is reached at which spontaneous decomposition of the bath occurs.

The materials used as buffers are closely linked with the complexing agents used. One or more ingredients frequently serve both functions. The main purpose of the buffers is to prevent a rapid increase in the acidity of the solution with an accompanying loss of deposition rate and changes in the characteristics of the deposits. Even with the use of appreciable concentrations of strong buffering agents, frequent additions of sodium hydroxide are needed to maintain the bath close to the optimum pH.

The complexing agents used are almost all organic acids, usually dicarboxylic acids. Their function is to reduce the concentration of free nickel ions. This helps stabilize the solution and prevent the precipitation of nickel phosphite. As the concentration of any one complexing agent is increased, the rate of deposition decreases. Therefore, combinations are often used to provide adequate complexing while maintaining rate levels. The exception to this rule is lactic acid, which in some formulations acts as an accelerator as well as serving the function of buffer and complexing agent.

Accelerators are used to overcome the rate depressing effects of complexing agents. Fluorides or sulfur-bearing compounds, such as thiourea, may be used. Concentrations are generally in the range 2 – 20 ppm.

A true electroless bath, in order to operate, must show some degree of instability. Given the right conditions, this instability may result in spontaneous decomposition, a violent reaction in which the rate increases exponentially and uncontrollably so that in a very short time the entire nickel content of the solution is reduced to a fine metallic powder. Even in the absence of complete decomposition, localized problems may occur as a result of localized overheating, local excesses of hypophosphite during additions, contamination with solids accidentally introduced, or the introduction of catalytic trace elements, such as palladium, from pretreatment processes.

Some of these problems can be prevented by proper circulation and filtration to keep the bath chemically and thermally homogeneous and free from particles.

A second preventive is the use of stabilizers. Ions such as Pb^{2+}, Cd^{2+}, Zn^{2+}, SCN^-, and CN^- have been used at concentrations of 1 – 10 ppm. Numerous other materials serving the same purpose have been found and in some cases patented. Compounds of selenium, tellurium, and a number of organic sulfur compounds, such as mercaptans, thiourea, xanthates, and sulfonates, have proved effective. Some of these stabilizers have been found to have secondary effects on the characteristics of the deposits and may improve surface luster.

Wetting agents are added to reduce the surface tension, thus bringing about the more rapid release of the hydrogen developed from the surface. This helps to eliminate pitting and gas streaking. Whatever type formulation is used, byproducts from the reactions and contaminants from pretreatment cycles and other sources eventually build up in the solution, making it necessary to discard and replace it. GUTZHEIT and others have devoted a great deal of research to methods of reclaiming solutions and establishing equilibrium conditions to permit unlimited operation, however, without complete success. The lives of the solution have been extended, but beyond certain limits they no longer function and cannot be reclaimed.

Rate is determined by the formulation, temperature, pH, and other factors such as agitation. An increase in pH also increases the rate up to the point where the hypophosphite spontaneously oxidizes and releases hydrogen, or the bath becomes so unstable as to decompose spontaneously.

The phosphorus content of the deposit varies with the operating conditions and the formulation between 2 and 14 wt % phosphorus, with most formulations yielding deposits in the 8 – 13 wt % range. Metallic ions other than nickel, introduced as additives or as contaminants, may codedeposit and alter the characteristics of the deposit. Antimony, bismuth, chromium, lead, mercury, and selenium may reduce the corrosion resistance of the deposits.

The deposits have a microcrystalline structure, usually laminar in nature, which appears to be Ni_3P in a matrix of nickel. The size of the Ni_3P crystals has been reported to range from 15 to 100 Å with an average size of 20 – 60 Å.

Heat treatment causes the nickel phosphide to segregate, increasing the hardness of the coating, developing greater wear resistance, and reducing the ductility. If the temperature exceeds 425 °C or is held close to that value for a considerable time, the deposit softens again and the ductility returns to the original level.

Although the corrosion resistance of the deposit varies from one formulation to another, it is almost always superior to that of electroplated nickel for equivalent thickness because above certain thicknesses electroless nickel is less porous than plated nickel. Great care must be taken with the pretreatment steps because of the effect of the pretreatment on porosity.

The following physical properties are typical for the deposits:

Phosphorous content	8 – 12 wt %
Hardness, as plated	550 – 650 VPN (100 g load)
heat treatable to	950 – 1050 VPN (100 g load)
Elongation before fracture	
as plated	0.5 – 2.0 %
heat treated	$\leq$6 %
Tensile strength	$>$700 MPa
Melting point	880 – 890 °C

The wear resistance of electroless nickel alloys is good in lubricated wear as long as the temperature remains low. Deposits may also be used to prevent galling between wearing surfaces provided only one surface is coated with electroless nickel.

Three typical formulations are shown:

Glycolic acid bath	
Nickel chloride ($NiCl_2 \cdot 6H_2O$)	30 g/L (4.0 oz/gal)
Sodium hypophosphite (NaH_2PO_2)	10 g/L (1.3 oz/gal)
Glycolic acid ($CH_2OHCOOH$)	35 g/L (4.7 oz/gal)
pH, adjusted with NaOH	4 – 6
Temperature	90 °C
Deposition rate	15 µm/h
Citric acid bath	
Nickel sulfate ($NiSO_4 \cdot 6H_2O$)	80 g/L (10.7 oz/gal)
Sodium hypophosphite	25 g/L (3.3 oz/gal)
Citric acid	95 g/L (12.7 oz/gal)
Ammonium chloride	50 g/L (6.7 oz/gal)
pH, adjusted with NaOH	4.8 – 5.8
Temperature	93 °C
Deposition rate	15 – 20 µm/h
Lactic – succinic acid bath	
Nickel sulfate	30.0 g/L (2.7 oz/gal)
Sodium hypophosphite	25.0 g/L (3.3 oz/gal)
Lactic acid	34.0 g/L (4.5 oz/gal)
Succinic acid	7.0 g/L (0.9 oz/gal)
Sodium fluoride	2.5 g/L (0.33 oz/gal)
Lead (Pb^{2+})	0.7 – 3.0 ppm
pH, adjusted with NaOH	4.5 – 4.7
Temperature	95 °C
Deposition rate	32 – 35 µm/h

Nickel – Boron Alloys. When a boron-containing reducing agent is used, a nickel – boron alloy is produced. These exhibit a higher as-plated hardness and have a melting point 200 – 400 °C higher than the phosphorus alloys. These nickel – boron alloys have not received the same level of industrial acceptance as the nickel –phosphorus alloys, but because of their different properties are used for special applications.

The formulations are very similar to the formulations using hypophosphite, with the exception of using a boron compound in place of the phosphorus compound. The original formulations were based on sodium borohydride. The baths had to be maintained at a pH $>$10.0, preferably 12 – 14 and required careful control to prevent solution decomposition.

Modern versions more often use dimethylaminoborane (DMAB). This reducing agent allows operation over a wider pH range, and the solutions have almost unlimited life since the breakdown products of the reducing agent have little or no effect on the operation of the solution. Deposition rates of 6 – 9 µm/h can be maintained. These rates are essentially independent of the nickel concentration and are mainly de-

pendent on the concentration of reducing agent. Two typical formulations are listed below:

Nickel sulfate	50 g/L (6.7 oz/gal)
DMAB	3 g/L (0.4 oz/gal)
Sodium pyrophosphate	100 g/L (13.3 oz/gal)
pH	10
Temperature	25 °C
Nickel chloride	24 – 48 g/L (3.2 – 6.4 oz/gal)
DMAB	3 – 4.8 g/L (0.4 – 0.64 oz/gal)
Ethylenediamine 50 %	18 – 37 g/L (5 – 10 oz/gal)
Potassium acetate	18 – 37 g/L (5 – 10 oz/gal)
pH	5.5
Temperature	70 °C

Hydrazine borane is also used in some formulations.

11. Chromating

Chromium, vanadium, molybdenum, and tungsten, when they are in their high valence states and soluble, have an unusual ability either to prevent corrosion or to limit the salt growth that occurs following corrosive action. Chromium(VI) compounds are the most widely used compounds of the group, and a whole series of chromate conversion coatings have been developed for various metals. Specifically, copper, brass, cadmium, zinc, and occasionally silver and gold are protected in this way. In general terms, the solutions consist of a soluble dichromate salt, such as sodium or potassium dichromate, and a catalyst similar to those used in chrome plating, such as SO_4^{2-}, F^-, or the other effective catalysts including complex fluorides or boric acid. Other anions may be added to alter the character of the film formed. The film is a colloidal gel that contains soluble chromium(VI), as well as salts of the base metal. The corrosion protection characteristics are dependent on the soluble Cr(VI) leaching out to protect the surface. If the parts are dried at a temperature close to or above 71 °C, the gel will dehydrate and the Cr(VI) reverts to an insoluble salt, and the protective mechanism is lost. Additionally, the gel will shrink as a result of the dehydration and exfoliate from the surface, becoming powdery and easily removed by abrasion. The original chromating solutions were relatively concentrated (120 – 240 g/L $Na_2Cr_2O_7$, 16 – 32 oz/gal) with catalyst in the ratio of 1 : 100). On zinc and cadmium, these produced iridescent yellow coatings that gave up to 72-h salt-spray resistance to the development of white corrosion salts. On copper, they provided resistance to the development of green salts of up to 24 h of salt spray, or up to 1000 h of 100 % humidity. Modern chromating solutions are almost all proprietary and operate at much lower concentrations. They fall into five categories:

1) Clear to bluish single dip chromates. Salt spray resistance ca. 24 h.
2) Clear leached type chromates. These are iridescent yellow chromates that are subsequently leached in a sodium hydroxide – sodium carbonate solution to provide a clear coating. Salt spray resistance up to 48 h.
3) Iridescent yellow chromates, single dip. Salt spray resistance up to 72 h.
4) Olive drab chromates, single dip. Salt spray resistance up to 144 h.
5) Black chromates. These may be single dip chromates in which the black color is provided by silver salts, which deposit microscopic amounts of silver in the gel. These chromates generally have less corrosion resistance than an uncolored chromate since the silver particles provide active electrochemical cells for the initiation of corrosion. Salt spray resistance 24 – 48 h.

There are also double dip systems in which an iridescent or olive drab coating is applied and subsequently dyed black using an organic dye.

Immersion times are from 10 to 30 s. Temperature and agitation affect the formation of the coating. Transfer time to the rinsing step can be important, and on automatic equipment where transfer times may run 30 – 45 s, special formulations may be necessary.

12. Oxide Coatings

12.1. Immersion

Immersion type oxide coatings are used mainly for appearance, as a paint base, or for their oil-retention characteristics.

Steel. Steel may be blackened in a high-temperature bath containing 480 – 840 g/L

(64 – 112 oz/gal) of a mixture of ca. 75 wt % sodium hydroxide and 25 wt % sodium nitrate. In this range, the solution boils under atmospheric pressure at 121 – 149 °C. The solution is controlled by monitoring the boiling point rather than by chemical analysis. Salts or water are added as required to maintain the boiling point and the solution is operated at the boil. Instead of 25 wt % sodium nitrate, 12 wt % sodium nitrate and 13 wt % sodium nitrite may be used.

The lower boiling points are obtained by including various sulfur-containing additives. The resulting oxide coating is somewhat less corrosion resistant as a result of the incorporation of iron sulfide in the film. Some of the sulfide-modified materials may also be used to blacken stainless steel. The resulting oxide, however, has relatively low corrosion resistance. The oxide coating is quite hard and therefore does not lend itself to use where decorative relieving is planned. There are proprietary immersion deposits available that are better for this purpose.

Following thorough rinsing, the oxide film should be coated with an oil, wax, or lacquer.

There are numerous gun blueing and gun browning formulas available in various craft handbooks. These are generally lengthy, labor-intensive procedures and are not used for production purposes.

Stainless steel can also be blackened in molten sodium/potassium dichromate at ca. 370 °C provided the parts are not adversely affected by the high temperature. The resulting oxide has good corrosion resistance, and the procedure is covered by several military specifications.

Copper. Copper may be blackened in a bath containing 120 g/L (16 oz/gal) of a mixture of 75 wt % sodium hydroxide and 25 wt % sodium chlorite at 93 – 100 °C. The black copper(II) oxide produced is acicular in form and presents a fuzzy appearance. On bright finished parts, this fuzzy nap disappears when lacquer is applied, restoring the lustrous appearance, or it may be laid down (not removed) by gentle buffing or tumbling in sawdust or corncob grit.

Brass may sometimes be blackened in the same solution but, depending on zinc content and metallurgical history, may not respond. Activation may be carried out by immersion in a bath containing 120 g/L of a mixture of 85 wt % sodium hydroxide and 15 wt % sodium chlorite operated at 93 – 100 °C for 5 – 10 min to dezincify the surface, after which the blackening bath will usually function normally.

Aluminum. Aluminum may be given an oxide coating by immersion by a number of different processes including the Alzac and Juratka processes. However, electrolytic processes are generally preferred.

12.2. Electrolytic Oxidation

Many different metals may be electrolytically oxidized or anodized, but in industrial practice the procedure is usually limited to aluminum, magnesium, and titanium.

12.2.1. Aluminum

Aluminum may be anodized in hundreds of different baths. Industrially, sulfuric, chromic, and oxalic acid, and mixtures of these, sometimes with added salts, are used. Sulfuric acid is probably the most widely used.

A wide variety of current forms and wave shapes may be used for the process, depending on the solution selected and the purpose of the anodic film. Direct current (d. c.), alternating current (a. c.), and d. c. with superimposed a. c. are all used in various processes.

Oxide coatings produced from *oxalic acid solutions* are hard, relatively nonporous, and thin, and have the highest dielectric strength. Such coatings have been used as insulation on high-voltage transmission wires. The process also requires the highest operating voltage, up to 65 V in some processes. Coloring the coating by subsequent dye absorption can be difficult, but some modified oxalic acid solutions have been developed which produce very attractive, startingly clear results. Others produce an opaque effect that is especially attractive in pastel shades.

Coatings produced from *chromic acid* solutions are somewhat dark in color, often have a yellow tinge, are intermediate in hardness and thickness between oxalic and sulfuric acid processes, and require operating voltages up to 40 V. The coatings may be colored by dyeing, but pastel colors are not generally obtainable. Chromic

acid anodizing is preferred by the military for anodizing assemblies with lap seams or other areas that may trap solution since any solution so trapped not only does not corrode the base metal but also provides chromium(VI) to act as a corrosion preventative. Chromic acid coatings, when sealed in a sodium dichromate solution, provide the highest corrosion resistance of any of the anodic coatings.

Sulfuric acid processes can produce the thickest, softest, most porous coatings. Because of this, they are the preferred type of coating where the coating is to be subsequently colored by dye absorption.

Hard anodizing is a special case of sulfuric acid anodizing in which the solution is maintained at a very low temperature. The coating is extremely hard and wear resistant. If maximum hardness is wanted, the coating is left in the unsealed condition since the sealing process reduces hardness.

As formed, the coatings are porous and absorptive. Advantage of this may be taken to color the coatings by absorbing dyes or forming pigments within the coating. Architectural colors (mostly browns and bronzes) may be developed as part of the anodizing process by using special alloys and solutions. The color is a function of the alloy, the anodizing solution, and the conditions of treatment.

Organic dyes, specially selected for color fastness, are available in almost all shades: pastels, imitation brass and bronze, gold, and deep shades including black. The depth of color may be controlled by the thickness and porosity of the coating (determined by the application times and temperatures), the dye concentration, pH of the dye bath, and dyeing time. For maximum color uniformity and light fastness, dyeing times should not be short; rather, the coating should be dyed to saturation and the depth of color controlled by adjusting the dye concentration. Normal conditions are 3 – 10 g/L (0.4 – 1.3 oz/ gal) of dye, pH 4.5 – 6.0 (electrometric), and a time of 5 min. For black dyes, the concentration may be 10 – 20 g/L (1.3 – 2.7 oz/gal) or more.

Light-fast *inorganic pigments* may be developed within the coating by a two-step dyeing process. The parts are successively immersed in salt solutions, which precipitate the pigment. Some typical combinations are the following:

Red brown – copper sulfate followed by potassium ferrocyanide.
Brown – silver nitrate followed by potassium dichromate or chromate.
Dark brown – lead acetate followed by ammonium sulfide.
Yellow – lead acetate followed by potassium dichromate or chromate.
White – lead acetate followed by sodium sulfate.
Blue – iron(III) sulfate or chloride followed by potassium ferrocyanide.
Black – cobalt acetate followed by sodium sulfide.

Other possible combinations can be drawn from a knowledge of inorganic pigment chemistry.

A development is the electrolytic deposition of tin and tin salts within the film to produce colors.

Whether the film is colored or not, the final step in the process is *sealing*, which closes the pores of the coating and prevents undesirable absorption.

Clear coatings may be sealed in distilled or deionized water. Coatings colored with organic dyes benefit from being sealed in a solution of nickel acetate, cobalt acetate, or a mixture of the two. The nickel or cobalt insolubilizes the dye, improves light fastness, and seals the coating.

Added corrosion resistance at the expense of developing some yellow color is obtained by sealing in sodium dichromate solution. Almost all chromic acid coatings, since they are intended for corrosion resistance, are so sealed.

A common problem in sealing is the development of *sealing bloom*, a powdery film that develops on the surface of the coating. It is due to the growth of aluminum salts out of the pores in the coating. It may be prevented by sealing to 75 – 80 % completion, allowing the final sealing to occur in air, or by incorporating a suitable bloom prevention material in the sealing solution. These are usually proprietary and are based on mild complexing agents for aluminum such as sodium gluconate, sodium gluco-heptonate, or one of the other compounds that are also useful for preventing the development of tank scaling in caustic etching solutions for aluminum.

12.2.2. Magnesium

Magnesium anodizing processes have been available for many years. They were, however, supplanted for many years by immersion chemical treatments, which gave equal or superior corrosion preventative and paint bonding characteristics. The chemical treatments still account for a high percentage of the coatings applied, but anodic treatments have been developed which produce relatively thick, dense, adherent, abrasion-resistant coatings. Two general types are in use: those based on modified acid fluorides and caustic types.

The *modified acid fluoride process* is covered by a U.S. military specification (Mil-M-45202) and is applied in three different forms:

1) Clear. A very thin 40 V coating suitable for use as a base for clear lacquers or paints and similar in appearance to clear anodizing on aluminum. Anodizing time is 1 – 2 min.
2) Low-voltage thin coating. Final voltage is 60 – 75 V to give the best combination of protective value and paint-base properties. Anodizing time is 2.5 – 5 min, depending on the alloy and the current density. The coating is light gray to pale green in color; thickness is 5 – 10 µm.
3) Full coating. Final voltage is 75 – 95 V. This type has the best combination of abrasion resistance, protective value, and paint-base characteristics. Coating is medium green in color; thickness is 23 – 30 µm.

Two types of solution are in use, and either direct current or alternating current may be used:

Ammonium hydrogen fluoride	240 g/L (32 oz/gal)
Sodium dichromate	100 g/L (13.3 oz/gal)
Phosphoric acid	9 % vol

For use with direct current the fluoride salt should be increased to 360 g/L (48 oz/gal).

Ammonium hydrogen fluoride	200 g/L (27 oz/gal)
Ammonium hydrogen phosphate	100 g/L (13.3 oz/gal)
Sodium dichromate	75 g/L (10.0 oz/gal)

For use with direct current, the fluoride salt should be increased to 270 g/L (36 oz/gal).

The bath must be heated to 82 °C to ensure complete solution of all ingredients. If allowed to cool during idle periods, the bath must be reheated to this temperature and thoroughly agitated before use. The bath does not operate below 60 °C, but may be operated up to the boil.

Best results are obtained if the process is carried out at a relatively constant current. Anodizing is therefore started at a low voltage, and the voltage continuously raised to maintain the desired current density until the desired coating is obtained. Between 2 and 50 A min dm^{-2} (20 – 500 A min ft^{-2}) is required, depending on the coating mass. The terminal voltage varies with the alloy and the current density, but the ampere minute requirement for any particular coating is a constant for any one alloy. After anodizing, parts are rinsed in cold and hot water and dried. If parts are to be left unpainted, or painted only in certain areas, they may be sealed in a water glass solution (7 wt % silicate) for 15 min at 93 – 100 °C.

The H.A.E. anodize treatment is typical of the *modified caustic treatments* and is covered by the same military specification as the acid treatment. It is applied with alternating current; direct current is not satisfactory. Again, three types of coating may be applied from the same bath with slightly different operating conditions:

1) Low voltage. A softer coating, smooth and olive-drab in color. Treatment time is 15 – 20 min at ca. 9 V, a current density of 4 A/dm^2 (40 A/ft^2) and a bath temperature of 60 – 65 °C.
2) High voltage (light coating). Similar to the low voltage coating, but tan in color. The bath is operated at 21 – 26 °C and cooling of the solution is generally required. The terminal voltage is 60 V at a current density of 1.8 – 2.0 A/dm^2 (18 – 20 A/ft^2), and processing time is ca. 8 min.
3) High voltage (hard coating). Brown in color and somewhat rougher than the low-voltage coatings. Terminal voltage is 85 V, current density is 1.8 – 2.0 A/dm^2 (18 – 20 A/ft^2), treatment time is 60 – 75 min, and temperature is 21 – 26 °C. Cooling is required.

The solution has the following composition:

Potassium hydroxide	165 g/L (22 oz/gal)
Aluminum hydroxide	34 g/L (4.5 oz/gal)
Potassium fluoride	34 g/L (4.5 oz/gal)
Trisodium phosphate	34 g/L (4.5 oz/gal)
Potassium permanganate	19 g/L (2.5 oz/gal)

After anodizing, the parts are rinsed thoroughly in cold water and then treated for 1 – 2 min in a solution containing 100 g/L (13.3 oz/gal) ammonium hydrogen fluoride and 20 g/L (2.7 oz/gal) sodium dichromate. The parts are then rinsed and dried. This posttreatment is necessary to neutralize the residual alkalinity in the coating for good paint adhesion and also to improve the protective value of the coating, particularly in unpainted areas.

12.2.3. Titanium

Titanium may be anodized in almost any conductive solution. A sodium hydroxide process has been developed in Britain; chromic acid-fluoride processes have been used; and a proprietary neutral salt solution is used to coat fasteners for aircraft. High voltages (90 – 110 V) are required to produce heavy coatings although some processes use as low as 10 V. As the coating builds in thickness, a whole range of interference colors develop, which have been used by artists working in titanium. Industrially, the coating is used to provide better adhesion for solid-film lubricants and paints and to prevent spalling of the surface.

12.3. Colors of Oxide Layers

Oxide layers, if they are thick enough, exhibit the natural color of the oxide. However if they are transparent and thin, light may be reflected and re-reflected within the coating to produce colored interference patterns, the colors varying with the thickness of the coating and the wavelength of the incident light – blues, greens, reds, and yellows – and often changing with the angle of incidence of the light and the angle at which the surface is viewed.

Two English artisans have done an extensive investigation of ways to produce various colored and textured finishes on various metals. They have collected hundreds of such formulae in a volume illustrated with color plates of the finishes described [7].

13. Testing of Electrodeposited Coatings

13.1. Quality Control

The production of quality metal finishes depends on the maintenance of a strict, comprehensive quality control program. This program should have as a minimum three phases: (1) solution control, (2) preplate inspection, and (3) postplate inspection.

Solution Control. Solutions must be analyzed on a regular basis and maintained by proper additions. Generallly, ± 10 % of the control concentration is adequate. However, some solutions require a narrower control limit, e.g., the chromic acid : catalyst ratio in chrome plating. Additions should be made during idle periods if possible. Otherwise, the salts should be dissolved separately and pumped or filtered into the bath. In this way, any solid particulate matter that has not been filtered out of the bath and has settled to the bottom is not disturbed by the addition process to cause rough deposits.

Proper solution control also requires periodic monitoring of brightener content and balance, and testing for the presence of impurities with proper corrective steps being taken as indicated by the test results. Maintenance of a uniform brightener level is particularly important. Consideration should be given to the use of brightener pumps – either continuous feed or connected to an ampere hour meter. If a continuous feed pump is used, it should be interlocked with some other piece of equipment that is on only when work is being processed, e.g., the rectifier control or the run switch of an automatic machine. Such pumps not only deliver more uniform plated deposits, but save considerable amounts of brightener.

Proper recording of analytical results is important. Trends that could eventually lead to solution problems and defective work cannot be detected from a single analysis, but will become evident when a number of analyses are seen at the same time. Graphing of analytical results

may be even more helpful in detecting these trends.

Similarly, records of rejection rates (quality defective parts) are important to serve as a baseline for troubleshooting procedures in the event that problems are encountered. Additionally, trends in these rejection rates can be seen and often point to a potential problem before it becomes critical.

Filtration should be either continuous or periodic, as required by the solution. An effective monitoring system for the filters should be implemented to ensure that they are cleaned on a regular basis so that flow rate and filtrate clarity is maintained.

A maintenance program for rectifiers and instrumentation also reduces costs. This should include cleaning and check of output for rectifiers, checking calibration of temperature controls, cleaning bus bars and connections, checking anodes or anode baskets for proper contact, condition of anode bags, etc.

Preplate Inspection. Conditions that cause defective work often exist before the parts are plated. Such conditions as poor buffing or polishing, excessive edge burrs, cracking or crack initiation in formed parts, excessive metal grain size, residual magnetism, and many other conditions can cause problems in plating or be the cause of parts being rejected after plating. These conditions should be detected and corrected before parts are processed.

Postplate Inspection. The minimum level of postplating inspection is a visual examination of some or all the parts for obvious visual defects, i.e., lack of brightness, pitting, peeling, blistering, etc. For work being plated to a specification, other tests must be added, e.g., thickness and/or thickness distribution, salt-spray resistance, abrasion resistance, or other specified characteristics.

In most of these tests, the specified property is not measured directly. Rather, some related characteristic is measured, and the results of this measurement are related to the desired property by comparison with a standard. Calibration of the measuring equipment is critical and should be repeated at intervals such that the calibration remains accurate.

Some tests, such as salt-spray and humidity test, require days to complete. Where specifications involve such tests, failures can be avoided by setting and observing other quicker inspection standards that are affected by corrosion resistance of the parts, e.g., zinc that is to be salt-sprayed can be inspected for thickness and color of the chromate coating. If proper standards for these supplementary tests are maintained, salt-spray failures are unlikely.

Some finishes, e.g., brass plating or anodized and dyed aluminum, require that a standard color be matched. Standards should be approved before production is started, and working standards provided to the inspectors. These working standards should represent the maximum allowable deviation from the original standard, thus setting limits for acceptance of work being inspected. Since these working standards may change with time as a result of use and exposure to light, they should be checked and replaced at intervals as required to maintain consistent output. The lighting of the inspection station (see Section 4.4) should be the same as that used to establish the master standards.

13.2. Thickness Testing

Deposit thickness may be tested by destructive and nondestructive methods.

13.2.1. Destructive Testing

Destructive tests include: (1) strip and weigh, (2) the dropping test, (3) the jet method, (4) the electrochemical stripping test, and (5) microscopic tests.

Strip and Weigh. This is most often used for precious metal deposits on small parts. A number of small parts are weighed, stripped in a stripping solution that does not attack the base metal, and weighed again. The area of the pieces is calculated, and the weight loss per unit area converted to thickness. This method provides an accurate measure of the average thickness of deposit.

A variation of the method does not involve weighing the pieces. The parts are stripped in the smallest workable volume of stripper, and

the stripping solution analyzed for the concentration of stripped metal. This concentration is converted to total weight of stripped metal and, using the area of the pieces, converted to an average thickness. This variation has the advantage that attack on the substrate is unimportant.

Dropping and Jet Tests. In the dropping test, a stripping solution is allowed to drop on the surface to be tested, and the number of drops required to expose the substrate is converted to thickness. In the jet method, a jet of controlled size is allowed to impinge on the surface, and the time required to expose the substrate is converted to thickness.

Both methods can be used to measure discrete areas on a surface. However, the area to be tested must have sufficient drainage that the stripping solution flows freely away from the test area.

Electrochemical Stripping Test. Various instrument manufacturers make electrochemical stripping equipment.

A small area of the surface is isolated by a rubber cup that also contains an electrode. An electrical contact is clipped to another area of the part. The rubber cup is filled with a special electrolytic stripping solution. At the beginning of the test, an electrical timer is set to zero, and a controlled current is applied to the system with the part being made anodic. When the metal being measured has been completely stripped from the test surface, the substrate is polarized by the stripping solution. The increase in voltage resulting from this polarization activates a relay that ends the test and stops the timer.

The stripping solution and the applied current are so selected that the thickness can be read directly from the timer. The method has the advantage that by properly selecting and changing the stripping solutions, successive layers of different deposits may be measured on the same spot. Charting the voltages needed to maintain the standard current may allow different layers of the same metal, e.g., nickel layers from different solutions, to be measured.

For most production purposes, the calibration given with the stripping solutions is of sufficient accuracy. For optimum accuracy, however, the instrument should be calibrated against standards plated from the same solution.

Microscopic Tests. The parts are mounted, polished, etched, and examined with a microscope. Deposit thickness is measured directly with a vernier in the eyepiece and a stage micrometer. The ASTM in its standard for such measurements, B-487, limits the use of the method to deposits at least 8 μm in thickness. This is one of the few direct measurements. However, it is subject to errors in polishing, etching, and observation, hence the restriction. Even with sophisticated equipment, the error apparently cannot be reduced to less than 0.15 – 0.25 μm.

13.2.2. Nondestructive Testing

Nondestructive thickness tests include: (1) magnetic force methods, (2) magnetic flux methods, (3) eddy current methods, (4) X-ray methods, and (5) beta backscatter methods.

Magnetic Force Methods. A magnetic method is only effective with nonmagnetic coatings on magnetic substrates or with magnetic coatings on nonmagnetic substrates. A magnet is brought into contact with the surface and the force required to release it is measured. This force must be compared against carefully prepared standards. Accuracy is affected by variations in the roughness of the surface, the substrate alloy, and for magnetic coatings the conditions under which the coating was deposited.

Magnetic Flux Measurement. These instruments measure the reluctance of a magnetic flux path passing through the coating and the substrate. They are used for the same coating – substrate combinations as the magnetic attraction methods, but have a greater range of thickness capability. Lower limit thickness is ca. 5 μm and upper limit about 1 mm. Calibration is important.

Eddy Current Methods. The probe generates a high-frequency electric field in a coil mounted in an open ferritic pot core. When the probe is in contact with a metallic substrate, eddy currents are induced in the metal. The magnitude of these currents depends on the distance

between the probe and the surface, which is essentially the thickness of the nonconductive or plated coating. These currents generate a magnetic field, which in turn interacts with the probe and produces current changes that are measured. These measurements can then be related to the coating thickness through the use of calibrated thickness standards.

Measurements are affected by the frequency used in the measuring probe, the conductivity of the coating and the substrate, the magnetic permeability of the coating and the substrate, and the roughness of the surface. Most manufacturers of these instruments do not recommend their use for conductive coatings on metal, but one manufacturer claims that if the differences in the conductivity of the coating and the substrate are sufficiently great, eddy current devices can be used when properly calibrated.

There are enough common characteristics between magnetic reluctance measuring instruments and eddy current instruments that at least one manufacturer builds a dual purpose instrument that can be switched from one mode to the other.

X-Ray Methods. Two X-ray methods are in use. One measures the X-ray fluorescence emanating from the coating, the other the X-ray fluorescence of the substrate. The fluorescence is produced by irradiation of the target area by a beam of X-rays. One of the frequencies of the expected stimulated radiation is selected for measurement and the result converted to thickness. The atomic number of the deposited metal affects the thickness range that may be measured; the higher the atomic number, the higher the upper limit for measuring thickness. The lower limit is less than 0.1 μm; hence, the method is often used for measuring gold. The upper limits are in the range of 1 – 100 μm, depending on the coating system. The accuracy can be ± 10 % or better.

Beta Backscatter Methods. These are similar to X-ray methods, but use a source of beta rays instead of X-rays.

13.3. Adhesion Tests

Adhesion is a micro phenomenon (see Section 5.1). It occurs between atoms or molecules. But by their very nature, adhesion tests are macro phenomena and therefore can only test the average adhesion across a surface. Further, there can be tremendously wide variations in the effectiveness of the part preparation cycle across the surface of the piece so that an area of excellent adhesion may be immediately adjacent to an area of zero adhesion. Adhesion tests must be combined with careful visual examination.

All adhesion tests are destructive tests and involve bending, gouging, grinding, or other methods of forcefully removing the plated layer. The results and the interpretation of the results are subjective, not absolute, and when used to evaluate production, are used as go/no go trouble shooting tests rather than for routine quality control. While there are a few tests that provide measured pull data, e.g., the Jacquet test, they involve the use of specialized and relatively expensive equipment and, with the exception of testing plated plastics using a modification of the Jacquet test, are rarely used except as research tools.

13.4. Corrosion Testing

No accelerated corrosion test can truly duplicate field corrosion conditions. As a result, correlation between performance in corrosion tests and performance in the field is almost never available. While a number of accelerated corrosion tests have been developed and are used as part of the performance requirement in specifications for plated coatings intended for outdoor exposure, confidence in the results appears to be lacking. However, as a general rule, parts that fail the corrosion test will fail in service, yet parts that pass the corrosion test may also fail in service. When failure occurs, it can often be attributed to insufficient plating thickness. Therefore, the corrosion performance test is usually supplemented by a minimum thickness requirement as part of the specification. Tests include: (1) the salt spray test, (2) the copper-accelerated acetic acid salt spray test, (3) the Corrodkote test, (4) the sulfur dioxide test, (5) the STEP test, and (6) the electrolytic corrosion test.

Salt Spray Test (ASTM Method B-117). Parts are subjected to a fog of 5 wt % sodium chloride solution under fixed conditions for specified periods of time.

Copper-accelerated Acetic Acid Salt Spray Test (Cass test, ASTM Method B-368). The 5 wt % salt solution is accelerated with 1 g of copper(II) chloride for each 3.8 L of salt solution, and the pH adjusted to 3.2 with acetic acid. The parts are then subjected to a fog of this solution under fixed conditions for specified periods of time.

Corrodkote Test. A paste containing copper(II) nitrate, iron(III) chloride, ammonium chloride, and kaolin is painted on the surface. After partial drying, the test piece is exposed in a humidity cabinet maintained at $100 + 2 - 3\,^{\circ}C$ and a relative humidity between 80 and 90 %. After cleaning the corroded surface, the corrosion sites are redeveloped in a salt spray or humidity cabinet. This test is specified as an alternate to the Cass test for automotive and other applications where severely corrosive environments are expected.

Sulfur Dioxide Test. Parts are exposed in a humidity cabinet maintained at 100 % humidity with SO_2 added to the atmosphere. The cabinet is heated to $40 \pm 3\,^{\circ}C$ for 8 h and cooled for 16 h in repeating cycles.

Simultaneous Thickness and Electrochemical Potential (STEP) Test. This test is used for the evaluation of multilayered nickel – chromium decorative coatings. It is not a corrosion test. The test consists of electrolytically dissolving the various layers and monitoring the potential changes as each layer is removed. These changes in potential can be interpreted in terms of coating performance and suggest corrective changes in the operating conditions of the plating solutions if necessary. The thickness of the nickel layers is also measured.

Electrolytic Corrosion (EC) Test. This is a rapid method for evaluating copper – nickel – chromium coatings on zinc-base or steel substrates. It is a potentiostatically controlled method of corroding the metal layers in a relationship that corresponds to outdoor exposure. Substrate attack may be observed by adding indicators to the electrolyte. An alternate method is to run the test for a specified period of time and assess the degree of corrosion by measuring the corrosion sites with an interference microscope. It is said to give the equivalence of one-year outdoor exposure in a few minutes.

13.5. Other Tests

Various other tests may be used for other requirements, e.g., abrasion tests for hard anodized coatings. The electronic industry in particular has a number of specialized tests designed to measure the durability and corrosion resistance of plated coatings used for contacts and other purposes. Solderability is a major concern in electronic manufacture, so there are a number of tests to determine ease of solderability, integrity of soldered connections, and the ability of a coating to maintain its solderability characteristics during the storage prior to assembly.

14. References

General References

The first three references contain extensive bibliographies.

Journals: The American Electroplaters and Surface Finishers Society (AESF) in the United States publishes *Plating and Surface Finishing,* and The Institute of Metal Finishing in England publishes the *Transactions of the Institute of Metal Finishing*. The annual index of these journals reveals finishing trends and sources of the latest information. Two other journals are *Metal Finishing* and *Products Finishing*. *Metal Finishing* publishes annually, usually in the February issue, a survey of technical developments during the previous year with an extensive bibliography (over 800 references in 1984).

Other sources: The AESF has an arrangement with a university to provide a data base service. A source often neglected is the sales literature and operating bulletins of supply companies, which, while obviously aimed at producing sales, often contains useful information in a condensed form.

1. Introduction

Electrochemistry of solute systems deals with the exchange of charge between an electrode and electron donors or acceptors present in the solvent and with ionic charge transfer through the solvent between two electrodes. Both phenomena, charge transfer and ionic conduction, are treated more extensively in the B Series under Electrochemical Reactors. The aim of this article is to describe the interaction of the fundamental phenomena in an electrochemical process, leading to the relatively complex macroscopic response of a process to changes in the process variables.

For example, current yields and energy consumption for the production of chlorate are determined by a multitude of factors that do not interest the theoretical electrochemist but that the electrochemical engineer must skillfully master in order to build a commercially attractive process. This process is determined simultaneously by (1) the electrode kinetics of anodic chlorine and cathodic hydrogen evolution, (2) the chosen current density and process temperature, (3) the conductivity of the electrolyte, i.e., the brine concentration, (4) the velocity of the electrolyte convection and the residence time of the electrolyte within the cell and any additional reaction vessel, and (5) the cell geometry, i.e., electrode spacing and detailed structure of the electrodes forming the electrolyzer walls.

Cell geometry and electrode structure define the cross section of the cell and affect the fluid dynamics of the streaming electrolyte. They determine the mass transfer of evolved chlorine from the anode and of hydroxyl anions from the cathode into the bulk of the electrolyte, and hence the macrokinetics of hypochlorite and chlorate formation.

2. Basic Laws and Equations

The cell voltage of any operating electrolyzer is composed of four terms: (1) equilibrium potential difference of the cell reaction $U_{0,\mathrm{c}}$, (2) anodic overpotential η_a, (3) cathodic overpotential η_c, and (4) ohmic voltage drop ΔU_Ω between cathode and anode.

$$U_\mathrm{cell} = U_{0,\mathrm{c}} + \eta_\mathrm{a} - \eta_\mathrm{c} + \Delta U_\Omega \tag{1}$$

The *equilibrium potential* of the cell reaction, $U_{0,\mathrm{c}}$, is determined by the Gibbs free enthalpy of the cell reaction and can be calculated fairly accurately by adding the equilibrium electrode potentials of the two electrodes, which are the standard potentials $E^0{}_i$ for the electrode reactions corrected for the concentrations or partial pressures of the potential-determining species according to *Nernst's equation.*

$$U_{0,\mathrm{c}} = \Delta G/zF = (E_\mathrm{a} - E_\mathrm{c})_\mathrm{eq} = \left[E_\mathrm{a}^0 + \frac{RT}{zF}\ln\left(c_\mathrm{ox}/c_\mathrm{red}\right)\right]_\mathrm{a} - \left[E_\mathrm{c}^0 + \frac{RT}{zF}\ln\left(c_\mathrm{ox}/c_\mathrm{red}\right)\right]_\mathrm{c}$$

The *anodic* and *cathodic overpotentials* can be envisaged to be composed of two terms: (1) concentration polarization η_conc as induced by concentration differences between the electrolyte at the electrode surface and the bulk of the electrolyte due to mass-transfer hindrance and (2) additional overpotential η_ct required to drive the charge transfer with the desired current density. Concentration polarization overpotentials can be calculated by the modified Nernst equation:

$$\eta_\mathrm{conc} = \frac{RT}{zF}\ln\left(c_\mathrm{ox}/c_\mathrm{red}\right)^{x=0} / \left(c_\mathrm{ox}/c_\mathrm{red}\right)^{x=\infty}$$

where x is the distance from the electrode. Here, $x = 0$ refers to the electrode surface, and $x = \infty$ refers to the bulk of the electrolyte.

2.1. Electrode Kinetics

Overpotential due to charge transfer η_{ct} may be obtained from the *Butler – Volmer equation*, which correlates current density and charge-transfer overpotentials:

$$j = j_0 \left[\exp\left(\eta_{ct} F \alpha^+ / RT\right) - \exp\left(-\eta_{ct} F \alpha^- / RT\right)\right] \quad (2)$$

The anodic and cathodic charge-transfer coefficients α^+ and α^- for simple electrode reactions, in which only one electron is exchanged between the electrode and the dissolved redox system, are close to 0.5, but may vary widely for reactions composed of a series of charge-transfer and chemical steps. For small overpotentials, the Butler – Volmer equation approaches

$$j = j_0 \left(\eta_{ct} F / RT\right) \left(\alpha^+ + \alpha^-\right) \quad \eta_{ct} \ll \left(RT / F \alpha^+\right)$$

For high overpotentials, one of the two terms usually outweighs the other, and the correlation is given by a single term describing either the anodic or the cathodic current density,

$$j = j_0 \exp\left(\eta_{ct} F \alpha^+ / RT\right) \quad 1 \gg RT / \eta_{ct} F \alpha^+ \quad (3a)$$

or

$$j = j_0 \exp\left(-\eta_{ct} F \alpha^- / RT\right) \quad -1 \gg RT / \eta_{ct} F \alpha^- \quad (3b)$$

Under these conditions the equation can be transformed into the familiar *Tafel equation:*

$$\eta = a + b \ln |j| \quad (4)$$

with a equaling ($RT/F\ \alpha$) ln j_0 and b equaling $RT/F\ \alpha$, where α is either α^+ or α^-. The overpotential for a given anodic or cathodic current density j is therefore determined simultaneously by the exchange current density j_0 and the "Tafel slope" b, and thus by the charge-transfer coefficient α.

2.2. Technical Electrocatalysis

2.2.1. Principles of Electrocatalysis

Simple charge-transfer reactions, like the one-electron oxidation or reduction of a dissolved metal ion to a solvated ion of higher or lower oxidation state, most commonly exhibit charge-transfer coefficients of ca. 0.5 and often possess activation enthalpies which are much lower than those of most chemical reactions so that the exchange current densities j_0 range from 10^{-3} up to 10 A/cm^2. Whenever the electrochemical reaction is more involved, i.e., when it is composed of at least two charge-transfer steps with at least one intermediate chemical reaction, then the reaction is likely to be kinetically hindered to a significant degree. This results in very low exchange current densities. Simple charge transfer, e.g., to dissolved partners of a redox system is only moderately sensitive to catalytic acceleration. Slow intermediate chemical reactions in multielectron electrode reactions however, that are usually hindered due to chemical kinetics, can often be accelerated very strongly by means of heterogeneous catalysis at the electrode surface.

Electrocatalysis and Formal Electrode Kinetics. Electrocatalytic action of the electrode material may have two different consequences, both leading to reduced overpotential at higher current densities:

1) The mechanism of the overall electrode reaction is kept unchanged but it becomes accelerated which is manifested in an increased exchange current density j_0 (Fig. 1B)
2) The electrocatalyst accelerates the overall rection by opening a new rection pathway. This is usually manifested by a change of the charge transfer coefficient, α, which is usually decreased, leading to reduced overpotentials at higher current densities although the exchange current densities are lower than for the uncatalyzed case (Fig. 1C) in this case

Chemical Catalysis and Electrocatalysis. It is the chemistry in electrochemical reaction mechanism, which is the most hampered, needing catalytic acceleration. Therefore electrochemical catalysis does not differ very much fundamentally and mechanistically from chemical catalysis and, apart from the fact that charge transfer rates and electrosorption equilibria depend exponentially on electrode potential. In many cases electrocatalysis and catalysis of electrochemical and chemical oxidation or reduction processes follow very similar if not the same pathways.

Figure 1. A) Determination of log j_0 by extrapolating the linear parts of the cathodic and anodic branches of the semilogarithmic current voltage plot. Electrocatalysis is manifested by increase of the exchange current density,j_0 or (B) by a decrease of the slope of the voltage – log current correlation (C)

Figure 2. H_2 Volcano curve: logarithm of exchange current density of H_2 reaction vs. enthalpy of hydroge adsorption at different metals
○ Acidic

Electrochemical Hydrogen Oxidation and Generation. Since electrochemical hydrogen oxidation and generation is coupled to the chemical splitting of the H_2 molecule or its formation from adsorbed hydrogen atoms, electrocatalysts for cathodic hydrogen evolution or its oxidation and catalysts for chemical hydrogenation are essentially the same: platinum and the transition metals of group 10 (VIII) of the periodic table. For catalysis and electrocatalysis the same correlation of catalytic activity interms of log j_0 and hydrogen adsorption enthalpies at the respective metal catalyst prevails, the volcano curve (Fig. 2) [9]. The catalytic activity of those metals is optimum which adsorb hydrogen only to a moderate extent and can thus assist H_2 splitting without hindering its desorption.

$$H_2O + e^- \rightleftharpoons H_{ad} + OH^- \quad (5a)$$

$$H_{ad} + H_2O + e^- \rightleftharpoons H_2 + OH^- \quad (5b)$$

The reaction sequence Volmer reaction (5 a) and Heyrovsky reaction (5 b) is not the only one possible. Desorption of the adsorbed hydrogen may also proceed according to the Tafel reaction (5 c) by purely chemical desorptive dimerization of two adsorbed atoms for which, however, the same fundamental considerations are valid

$$2\,H_{ad} \rightarrow 2\,H_2 \quad (5c)$$

Oxygen electrochemistry, i.e., anodic oxygen evolution and cathodic reduction of dioxygen as well as anodic oxidation of organics are catalyzed by the same metals or metal oxides. The latter are also used in chemical catalysis for catalytic oxidation of organic compounds. These

catalysts/electrocatalysts undergo relatively easily redox conversion with oxygen or are oxidized anodically to a higher valency state at potentials which are close to the oxygen equilibrium potential, in this way facilitating the release of oxygen molecules or the transfer of oxygen from oxidized surface groups of the catalyst to organic substrates Eqs. (6 a) – (6 d). The relation overpotential vs. reaction enthalpy for different transition metal oxides is shown in Figure 3. Going from lower to higher oxides a type of volcano curve of anodic O_2-evolution, is obtained [10].

$$Me + H_2O \leftrightharpoons MeOH + H^+ + e^- \quad (6a)$$

$$MeOH \leftrightharpoons MeOH + H^+ + e^- \quad (6b)$$

$$2\,MeO \leftrightharpoons MeO + O_2 \quad (6c)$$

$$6d2\,MeO + RH \rightarrow 2\,Me + ROH \quad (6d)$$

Figure 3. O_2 Volcano curve: overpotential at 0.1 mA/cm^2 vs. formation enthalpy of formation of higher from lower valent metal oxide

Utilization of Porous Electrocatalyst Particles In chemical heterogeneous catalysis of gas-phase reactions highly porous catalysts with particles of millimeter to centimeter size are used. In practical electrocatalysis, in particular in fuel cells, highly porous catalyst layers are employed as well. Accounting for the low diffusion coefficients in liquid electrolytes, 10^{-5} cm^2/s vs. 1 cm^2/s in gases, catalyst slabs which are completely flooded by the respective electrolyte have to be much smaller, i.e., of micrometer instead of centimeters size [11]; otherwise the catalyst would be utilitzed only to a very low degree.

A question of concern common to heterogeneous catalysts used in chemical catalysis and porous electrocatalytic coating is the problem of effective catalyst utilization. If the thickness of the porous catalytic coating or the diameter of the porous particle or slab does not properly match the mean diffusion length of consumed or produced species then the inner surface of the catalyst is no longer supplied sufficiently with substrate or becomes electrochemically inactive due to product accumulation and concentration polarization in the pores. In chemical engineering, the Thiele-modulus Φ_{Th} is used as a characteristic number defining the degree of utilization of a porous catalyst particle (Eq. 7 a).

$$\Phi_{\mathrm{Th}} = L\left(\frac{k}{D}\right)^{1/2} \quad (7a)$$

Where L is the pore lenght, coating thickness, or radius of the porous particle; k the volume-related rate coefficient of first order reaction; and D the effective diffusion coefficient of the reactant in the porous matrix.

For $\Phi_{\mathrm{p}} > 3$ the catalyst utilization η_{c} decreases according to a limiting $(\Phi_{\mathrm{Th}})^{-1}$ law. In a similar way the elctrochemical Thiele modulus $\Phi_{\mathrm{p,el}}$ (Eq. 7 b) is a measure for the utilization of porous electrodes in a particular fuel cell electrode of thickness L or nanoporous pellet of diameter L, which constitute a fuel cell electrode.

$$\Phi_{\mathrm{p,el}} = L\left[j\,(\eta)\,a/D\nu_{\mathrm{e}}Fc\right]^{1/2} \quad (7b)$$

(The corresponding relationship for other porous, gas evolving electrodes is mathematically more complex).

Where $j(\eta)$ denotes current density at overpotential η; a the inner electrode surface per unit volume of porous electrocatalyst; c the concentration of reactant in the electrolyte bulk; and ν_{e} the stoichiometric number of electrons for the given electrode reaction.

For a given overpotential η the the quantity $j(\eta)$ increases approximately linearly with the exchange current density j_0. For hydrogen evolving highly porous Raney nickel coatings (where j_0 equals roughly 10^{-4} A/cm^2), an overpotential of 100 mV, and a pore length $L = 1$ µm, $\Phi_{\mathrm{el,p}}$ approaches or exceeds 1 and therefore deeper pores (or thicker coatings) are no longer fully utilized. With platinum metals, which are much better catalysts than nickel ($j_0 > 10^{-2}$ A/cm^2), a dense but very thin ($d < 1$ µm) coating can be applied instead of a porous coating. The natural roughness of smooth coatings (1 µm) already matches the effective pore depht which can be fully utilized.

Functioning, Longevity, and Application of Electrocatalyst Coatings of Gas Evolving Electrodes. Electrocatalysts, composed of highly active precious metals are usually applied to the metal support (constituting the electrode proper) in the form of thin coatings, amounting to catalyst loading of milligrams per square centimeter or less. Longterm stability and firm adhesion to the support of such coatings is as important as their catalytic activity. Longevity of electrocatalyst coatings might be impaired by a number of different effects. Most important are (1) poisoning, (2) corrosion, (3) erosion, and (4) loss of internal surface by sintering and Ostwald ripening. *Poisoning* can only be reliably mitigated by using carefully purified electrolytes, raw materials, and (in fuel cells) anode and cathode gases. *Corrosion* is often a serious problem, in nonsteady condition, for instance off-times. Here redox reactions of the catalyst surface arising from floating potential render the catalyst material thermodynamically unstable or more soluble in the electrolyte than under operating potential. For instance trivalent cobalt contained in oxides (e.g., in spinels such as $NiCo_2O_4$ or Co_3O_4) is insoluble in aqueous, caustic solution, but becomes unstable at a more cathodic (i.e., more negative) potential. Cobalt(III) reacts with water under relaese of O_2 and is reduced to Co(II), which is soluble in strongly alkaline solution due to formation of $Co(OH)_4^{2-}$. *Erosion* by itself and coupled to corrosion may become a serious problem whenever electrochemical gas evolving is the main or a side reaction. Erosion is a problem if the electrode is exposed to a rapidly flowing electrolyte – in particular if the electrolyte is contaminated by dispersed solid matter. Erosion can be counteracted by modifying the structure and composition of the coating increasing its strenght and adherance and by influencing gas bubble formation in a way which removes the physical strain on the electrode due to bubble overpressure and violent two-phase flow. *Loss of internal surface* of highly porous coatings – for instance Raney nickel coatings – by slow recristallization can sometimes be prevented by internal or external dispersion hardening, i.e. by interdispersion of a second electrocatalytically inactive, oxidic highly dispersed powder which hinders creep or surface diffusion of the metallic catalyst material which would lead to agglomeration and surface loss.

The surfaces of oxidic redox catalysts which typically accelerate anodic oxygen or chlorine evolution or mediate anodic oxidation of organic substances, act catalytically as a whole not depending on active sites. They catalyze the respective reactions with every surface metal atom exposed to the electrolyte. For this type of electrocatalysts physically reinforcing the coating and strenghtening their adherance to the support is imperative. This is achieved by application of appropriate interlayers (e.g., SnO_x or TiO_y between RuO_2 and Ti-electrodes) or mixing the catalyst with inert valve metal oxides.

2.2.2. Technical Electrodes

2.2.2.1. Electrocatalytically Activated Dimensionally Stable Chlorine Evolving Electrodes

Electrocatalysis and Selectivity of Anodic Chlorine Evolution at RuO_2 Anodes. Figure 4 compares the current – voltage curves of anodic chlorine evolution measured at graphite and RuO_2 anodes in brine solution of a concentration of 300 g NaCl/dm^3, which is typical for chloralkali electrolysis. The overpotential at the RuO_2 anode is much smaller and mainly due to concentration polarization. Details of the electrocatalytic reaction are given in [11, 12, 13, 15]. The mechanism is likely to be similar to that one described [16], (Eqs. 6 a – 6 c) for anodic oxygen evolution. The same type of mechanism is also operative with anodic O_2 evolution at RuO_2 anodes. At pH 2 (the lowest pH value maintained in chlor alkali electroysis anolytes) the equilibrium potential of the oxygen anode is more cathodic than that of the chlorine electrode (+ 0.96 V vs. normal hydrogen electrode compared to + 1.26 V). Therefore, it is of ultimate importance that RuO_2 catalyzes chlorine evolution to much higher extent than oxygen evolution. However, at higher anolyte pH the oxygen potential becomes still more cathodic (60 mV/pH-unit). Thus, catalyst formulations are changed to increase the catalytic activity for the Cl_2 reaction over that of the O_2 reaction when dilute brine (30 g/dm^3 for NaOCl production) or seawater (Cl_2 production on board ships for desinfection) are electrolyzed. An increase of the Cl_2 selectivity is brought about by

adding small amounts of Pt and IrO_2 to RuO_2 or using anode coatings based on MnO_2.

Figure 4. Semilogarithmic current density overpotential correlation of anodic chlorine evolution on graphite and RuO_2 coated titanium anodes

2.2.2.2. Oxygen Evolving Anodes

Technical Processes with Anodic Oxygen Evolution. Oxygen evolution is the counter electrode reaction in hydrogen production from alkaline solution and in cathodic electrowinning of metals from acid aqueous solution. Examples for the latter are electrowinning of zinc, copper, tin, or lead. Water electrolysis usually is performed in concentrated alkaline solutions (30 wt % KOH), whereas the electrolytes used in metal electrowinning are moderately to strongly acidic (ca.1 M H_2SO_4). Therefore, the electrode support materials and electrocatalysts are different for these two different types of electrolysis processes. In alkaline electrolysis stainless steel or nickel is used as supporting electrode material for advanced water electrolizers, where materials of improved corrosion resistance are required. For oxygen evolution from acidic electrolytes the traditional anode material – lead, passivated by in-situ formed PbO_2 – is becoming superseeded by catalyst-coated titanium anodes.

Electrocatalysis of Oxygen Evolution in Advanced Alkaline Water Electrolysis.

Coatings Containing Cobalt and Iron Oxides. In different transition metal oxides and mixed oxides (Co_3O_4, Ni_2CoO_4, etc.), which possess a relatively low solubility in alkaline solution, the redox potentials of Co(II)/Co(III)/Co(IV) oxides are relatively close to the equilibrium potential of oxygen. Because of this unique characteristic, cobalt oxides are able to catalyze anodic oxygen evolution very effectively according to Krasil'chshikov's mechanism.

Figure 5 compares the current voltage curves of anodic oxygen evolution at three different temperatures in 30 wt % KOH using RuO_2 and three different coatings containig cobalt oxide on nickel.

Although RuO_2 has the highest catalytic activity exhibiting the lowest anodic overpotential (see curves D), it is not stable in caustic solution and dissolves due to anodic formation of RuO_3 within several days. All mixed oxides containing Co show anodic overpotential close to that of the spinel phase Co_3O_4. This magnetitic oxide, however, is not stable at potentials below ca. + 0.5 V vs. the reference hydrogen electrode (RHE)

$$Co_3O_4 + 6\,OH^- \longrightarrow 3\,Co(OH)_4^{2-} + 1/2\,O_2$$

forming soluble, complexed cobalt(II).

As the dissolved cobalt is deposited at the cathode, it is completely transferred from the anode to the cathode after repeatedly cycling the electrolyzer. Cobalt oxide-coated electrodes have to be protected against dissolution in off-times by applying a protective polarization.

Figure 6 compares the current – voltage curves measured using mixed iron oxide – cobalt oxide coatings with those measured on pure Co_3O_4 and Fe_2O_3 coatings. Iron(III) oxide is a sizably better catalyst than cobalt spinel. Fe_2O_3 has, however, a relatively high solubility (of several 10^{-6} M) in aqueous concentrated KOH solution so that because of dissolution of the anode coating and cathodic iron deposition, the catalyst is readily transferred from the anode to the cathode. This renders Fe_2O_3 inherently unstable in alkaline water electrolizers. Coatings which contain both iron and cobalt are much more stable and show catalytic activities even better than that of Fe_2O_3. The longevity of this type of coating is improved to a tolerable level of some thousand hours by decreased cobalt and iron solubility.

Catalyst-Coated Titanium Electrodes for Oxygen Evolution from Acid Solutions. Catalyst-coated titanium anodes can be advantageously used for oxygen evolution from acid solutions. The anode support is passivated by a

Figure 5. Semilogarithmic current potential correlation for anodic oxygen evolution from 30 wt % caustic potash at three different temperatures measured at nickel anodes with different metal oxide coatings
a) 50 °C; b) 90 °C; c) 130 °C

protective layer of TiO_2 and a suitable electrocatalyst coating reduces the oxygen overpotential substantially.

Figure 6. Semilogarithmic current voltage correlations of anodic oxigen evolution at 90 °C from 30 wt % KOH at smooth nickel anodes coated with: (a) Co_3O_4, (b) Fe_2O_3 and (c) a mixed oxide containing iron and cobalt together in roughly 1:1 molar ratio

In solutions containing approximately 20 g H_2SO_4 per liter at temperatures up to 40 °C titanium anodizes rapidly, forming a protective TiO_2 layer with time-independent thickness of fractions of micrometers. Between 50 and 70 °C continuous film growth is observed and titanium begins to dissolve actively above 70 °C. Consequently, metal-winning and metal-plating electrolyses with anodic O_2 evolution are operated at relatively low current densities allowing for relatively low process temperatures (< 40 °C) because heating by electricity passage is kept low. RuO_2 is an excellent electrocatalyst in acid solutions for anodic oxygen evolution. It is, however, oxidized and carried away in the form of relatively volatile RuO_4. Therefore, RuO_2 needs to be stabilized. Pt – Ir oxides with added TiO_2 and Ta_2O_5 – Nb_2O_5 as mechanical stabilizers are today used for anodic oxygen evolution in acid electrolytes. This type of anodes is still restricted to relative pure electrolytes, e.g., in anticorrosive tin or zinc steel-sheet plating in the automobile industry. Catalytic coatings composed of IrO_2 and Ta_2O_5 show a life time optimum at a composition of 70 wt % IrO_2/ 30 wt % Ta_2O_5. Exchanging tantalum for titanium as base metal significantly improves the stability of the combination support – coating. Such electrodes reduce the oxygen evolution

overpotential by approximately 0.5 V allowing to save more than 30 % of the energy costs which would be consumed by using conventional PbO_2 (Ag) anodes.

Water electrolysis, with hydrated cation exchange membranes (Nafion) (→ Hydrogen, Chap. 4.2.3.) cannot dispense with noble metal oxides. IrO_2 and mixtures of RuO_2/IrO_2 have succesfully been applied.

2.2.2.3. Electrocatalysis of Cathodic Hydrogen Evolution

Cathodic hydrogen evolution is the reaction of anodic chlorine evolution in chlor alkali elctrolysis. Hydrogen evolution is expected to become superseeded by the energy saving cathodic oxygen reduction only after a decennium of further development and only if energy prices will continue to increase. The chlor alkali electrolysis process is by far the most important source of electrolytically generated hydrogen, because hydrogen from water electrolysis usually cannot compete cost-effectively with hydrogen produced by steam reforming. Cathodic hydrogen evolution is also of some significance as counter electrode reaction in anodic organoelectrosyntheses.

Electrocatalyst Coating for Hydrogen Evolution from Alkaline Solution. Nowadays the following catalyst coatings are relevant for hydrogen evolution from alkaline solutions:

1) Nickel sulfide (NiS_x)
2) Raney nickel
3) Nickel alloys containing molybdenum
4) Oxidic coatings containing platinum metal oxides in particular RuO_2
5) Doped nickel oxide

Due to their relatively low costs the most frequently applied electrocatalysts are nickel sulfide and Raney nickel for alkaline conditions.

Nickel Sulfide Coatings. Two different methods are used for preparation of nickel sulfide coatings: cathodic deposition of NiS_x and chemical sulfidization of the nickel electrodes. Galvanic deposition is based on cathodic codeposition of nickel and sulfur from baths containing sulfur donors such as thiocyanate ion, thiourea, or thioglycol according to Eq. (8 a)

$$Ni^{2+} + x\,RS + 2e^- \longrightarrow NiS_x + x\,R \tag{8a}$$

The deposit is a mixture of different nickel sulfides together with amorphous nickel. The catalytic activity of the different NiS_x-phases increases with their sulfur content. Sulfidizing nickel in an atmosphere containing dihydrogen sulfide also creates smooth and close nickel sulfide layers mainly composed of NiS.

Nickel sulfide coatings are thermodynamically unstable at the hydrogen equilibrium potential. In aqueous alkaline solutions at hydrogen evolving cathodes all NiS_x-phases are reduced eventually according to Eq. (8 b) to highly disperse nickel which has properties in common with Raney nickel.

$$NiS + 2e^- \longrightarrow Ni + S^{2-} \tag{8b}$$

In so far the initial catalytic activity of the NiS_x coating is of little relevance and the real catalyst is highly dispersed nickel. Nickel sulfide coatings can only be used in nonpressurized electrolyzers working at relatively moderate temperatures (80 °C) because the cathodically released sulfide ions are aniodically oxidized to sulfate anions, which cause stress corrosion cracking with the steel parts of the electrolyzer.

Raney Nickel Coatings.

Precursor Alloys and Fabrication of Coated Cathodes. Raney nickel was introduced more than 30 years ago as an anodic electrocatalyst for alkaline fuel cells by Winsel and Justi [17]. Since more than 20 years it is used as catalytic coating for hydrogen evolving cathodes in chlor alkali electrolysis and alkaline water electrolysis. The operation conditions of the cathode are almost the same in both technologies as the catholyte contains 20 to 30 wt % NaOH or KOH and the process temperature is between 70 and 90 °C.

Although at least four different technologies for production of Raney nickel coated cathodes (cold rolling, flame spraying, Zn and Al-melt dipping, cathodic deposition of Ni/Zn-precursor alloys) have been described, only cold rolling and cathodic deposition of precursor alloys are used for commercial production.

Utilization of the Catalyst in Raney Nickel Coatings. Compared to platinum metals (e.g., Pt or Ru) which exhibit exchange current densities of the hydrogen evolution reaction in caustic electrolytes at 30 °C of the order of 10^{-3} to 10^{-2} A/cm^2, nickel is only a moderately active electrocatalyst with j_0 ranging from 5 to 7×10^{-6} A/cm^2 at ambient temperature. Therefore, considering a ratio of the exchange current densities of Pt and Ni of 10^2 to 10^3 a naive estimate would predict comparable activities of smooth Pt-metal cathodes and Raney nickel cathodes, provided the catalytically active inner surface of the Raney nickel coating would amount to 100 to 1000 cm^2 per square centimeter electrode surface. In practice, however, the internal surface of nanoporous Raney nickel catalyst coatings is usually utilized to no more than some percent. This low degree of catalyst utilization is due to slow diffusive mass transport of electrogenerated dissolved hydrogen out of the nanopores of the catalyst. The highest hydrogen concentration level in the pores is the concentration determined by the applied cathodic overpotential η according to Nernst's law (Eq. 9)

$$c_{\lim} = c_0 \exp\left\{\frac{-F\eta}{2RT}\right\} \tag{9}$$

with c_0 equaling the H_2 saturation at 0.1 MPa H_2 pressure.

Since the concentration of dissolved hydrogen in the pore increases with increasing pore depth the effective local cathodic overpotential diminishes due to concentration polarization according to Eq. 10, the overpotential η_x being always negative at H_2 evolving cathodes.

$$\eta_x = \eta_0 + \frac{RT}{2F} \ln \frac{c_x}{c_0} \tag{10}$$

The current density decreases to nil as the hydrogen concentration in the pore approaches its limiting value.

Figure 7 depicts the calculated current density, overpotential, and hydrogen concentration distribution in an assumed ideal (straight cylindrial) Raney nickel pore of a pore diameter of 2 nm and assumed virtual infinite depth calculated with an exchange current density of 10^{-4} A/cm^2, a value which is assumed to be valid for nickel at 80 to 90 °C. As can be derived from the current density distribution, the contribution of the pore walls to cathodic hydrogen evolution becomes negligible beyond 10 µm pore depth (Fig. 7D), so that a perfect, undivided Raney nickel coating of 100 µm thickness, can be utilized to only 7 to 8 %. This is the reason, why the fissures and cracks (tertiary structure of the catalyst) formed in Raney nickel coatings during the leaching process are important for improving its utilization. The utilization of gas evolving nanoporous catalysts increases with current density.

Performance and Aging of Raney Nickel Coatings. Raney nickel coatings obtained by relatively slow reduction of nickel sulfide during cell operation, which lasts for several hundred hours, shows almost no deterioration over more than 3000 h. In contrast, Raney nickel coatings formed by relatively fast caustic leaching of Ni – Zn precursor coatings deteriorate sizeable during long-term operation. This difference is very likely due to the more open and perturbed structure of the quickly formed catalyst, which causes restructuring and recrystallization accompanied by surface losses with time. Recrystallization may be retarded by dispersing TiO_2 or other metal oxides throughout the porous structure. This measure can only be used for cold-rolled or plasma-sprayed, not for cathodically deposited precursor coatings.

Coatings of Platinum Metal Oxides. Dimensionally stable RuO_2 anodes have been succesfully used also for cathodic hydrogen evolution. These electrodes are characterized by small Tafel slopes, low overpotential, and in particular insensitivity to iron poisoning. Ruthenium oxide is thermodynamically unstable and is reduced to ruthenium metal at hydrogen equilibrium potential. The metal becomes the catalyst proper although the underlying metal oxide layer keeps unchanged. It is the insensitivity of ruthenium metal to iron poisoning and the metallic reservoir stored in the bulk of ruthenium oxide which makes DSAs uniquely effective hydrogen evolving cathodes.

Active Coatings of Flame-Sprayed, Doped Nickel Oxide. Asahi Glass reports on the development and commercial use of electrodes covered by catalytically active nickel oxide coatings which are said to be fabricated by flame spraying. No detailed information of the composition, morphology and phase-content of the

Figure 7. A) Schematic of straight nanopore; B) Concentration increase of dissolved hydrogen in the depth of a cathodically active nanopore; C) H_2 concentration and effective overpotential; D) Current density distribution in the nanopore

coating are communicated. The electrode coating is said to deteriorate slowly by progressive reduction to metallic nickel. Life times of three years in chlor alkali electrolysis membrane cells are reported by the manufacturer.

Platinum and Platinum Metal Cathodes in Membrane Water Electrolyzers. In acidic electrolytes only noble metals, and in particular the platinum metals, are resitent under unpolarized conditions and can be used as electrode materials for hydrogen evolution. Platinum in particular is a unique electrocatalyst for H_2 evolution in strongly acidic environment as prevailing in perfluorinated sulfonated polymer membranes used as solid polymer electrolyte in membrane electrolyzers (see Section 4.2).

2.2.2.4. Electrocatalysis of Cathodic Oxygen Reduction and Anodic Hydrogen Oxidation in Fuel Cells (→ Fuel Cells)

Anodic hydrogen oxidation and cathodic oxygen reduction is kinetically hampered at low temperature, so that anodic hydrogen oxidation in alkaline fuel cells (AFCs), proton exchange membrane fuel cells (PEMFCs) and phosphoric acid fuel cells (PAFCs) demands catalysts of highest activity, that means platinum metals and platinum in particular. Working temperatures of molten carbonate fuel cells (MCFCs) and solid oxide fuel cells (SOFCs), however, are high enough that the cheaper nickel metal – a much poorer catalyst than Pt – can be used in the form of relatively coarse, sintered electrodes. Platinum is indispensible as catalyst, also for cathodic oxygen reduction in low temperature fuel cells, whereas the cathodic electrocatalysts in MCFCs and SOFCs are lithiated nickel oxide and lanthanum – manganese perovskite, respectively – which are relatively cheap *p*-type semiconductors.

Structural Design of Gas Diffusion Electrodes in Low Temperature Fuel Cells. Typically, the electrodes of low temperature fuel cells contain a bimodal pore structure, comprising nanopores in the catalyst particles and micropores between the particles. They are usually constituted of PTFE bonded nanoporous catalyst particles, usually Pt doped active carbon agglomerates (Fig. 8). The nanopores are flooded by the electrolyte, the micropores are free of electrolyte and conduct the working gases to the surface of the nanoporous catalyst particles, that are covered by a thin electrolyte film. The electrolyte in the flooded catalyst particles together with the electrolyte film on their surface form a coherent electrolyte phase. The electrolyte es-

tablishes a good connection between the electrode, the electrolyte filled interelectrodic gap, and the counter electrode on the one hand and the gas-filled pores connect the interior of the electrode to the gas lumen on the other hand.

Kinetic Aspects of Cathodic Oxygen Reduction at Low Temperature (T < 250 °C).

Stepwise Cathodic Reduction of Oxygen. Anodic oxygen evolution and the cathodic oxygen reduction are expressedly hindered at low temperatures so that significant overpotentials must be applied to perform the respective reaction with measurable velocities and current densities. The consequence is that microscopic reversibility is not established and oxygen reduction and anodic oxygen evolution proceed to different reaction routes.

It is almost impossible to establish the equilibrium potential of the oxygen electrodes in aqueous electrolytes (+ 1.23 V vs. reference hydrogen electrode, RHE). Usually at zero current density a potential of ca. 0.95 V vs. RHE is obtained which is established by mixed reactions, with the main reactions being the reduction of oxygen to hydroperoxide.

In *acidic media* protonation of oxygen followed by one-electron reduction is the rate limliting CE step for oxygen reduction.

C	$O_2 + H^+ \leftrightharpoons O_2H^+$	(11 a)
E	$O_2H^+ + e^- \rightarrow O_2H$	(11 b)

Where C denotes a chemical and E an electrochemical step with charge transfer.

Electrocatalyzed oxygen reduction proceeds always in the adsorbed state.

Almost in any case of electrocatalyzed oxygen reduction hydrogen peroxide is observed as a byproduct if it is not the main product – as for instance in the case of oxygen reduction in alkaline solution on graphite cathodes.

Here the two-electron ECE sequence

$(O_2H^+)_{ad} + e^- \rightarrow (O_2H)_{ad}$	Electron transfer	(12 a)
$(O_2H)_{ad} + H^+ \rightarrow (H_2O_2^+)_{ad}$	Chemical reaction	(12 b)
$(H_2O_2^+)_{ad} + e^- \rightarrow (H_2O_2)_{ad}$	Electron transfer	(12 c)
$(H_2O_2)_{ad} \rightarrow (H_2O_2)_{dissolved}$	Desorption	(12 d)

is so fast, that it cannot be resolved by usual electrochemicals methods available for electrode kinetic investigation, which have a time resolution of not better than 1 ms. The four-electron reduction of oxygen may be due to fast catalytic disproportionation of hydrogen peroxide, Eq. (13), and subsequent two-electron reduction of oxygen. This chemical diproportionation reaction is catalyzed by noble metals including silver and in particular platinum metals (stable in alkaline and acidic solution), and by a number of transition metal oxides, e.g., Fe_3O_4, MnO_2, Co_3O_4, and perovskites and magnetites containing NiO, FeO, MnO_x which are, however, only stable in alkaline solution

$$2\,H_2O_2 \rightarrow 2\,H_2O + O_2 \qquad (13)$$

Although $2e^-$ reduction with fast, chemically catalyzed H_2O_2-disproportionation seems to be the mechanism of highest importance, hydrogen peroxide can also be electrocatalytically reduced to water according to Eq. (14)

$$H_2O_2 + 2e^- \rightarrow 2\,OH^- \quad (14)$$

in a second, fast ECEC sequence, similar to (12 a) – (12 d) but accompanied by splitting of the O–O bond.

Metal Catalysts for Cathodic Oxygen Reduction. Electrocatalysis of anodic evolution and of cathodic reduction of oxygen proceeds in most cases of practical importance not on metallic, but on oxidized surfaces. Platinum like all other "noble" metals becomes already oxidized at potentials which are 0.2 mV more cathodic than the oxygen potential which is + 1.2 V vs. RHE. Other platinum metals, Rh or Ru and silver are even less noble. These oxide layers are the electrocatalysts proper for oxygen reduction. Most of the platinum metals, e.g., Pt, Rh, Ru, and Ir are corrosion resistant and do not dissolve in acidic solution (Pt not even in 100 % phosphoric acid at 200 °C). Silver is also a good electrocatalyst, which may, however, only be used in alkaline solution. Even there, silver cathodes and silver containing catalysts have to be protected from oxidation of the metal by keeping them permanently (in particular in off-time of the fuel cell) at a cathodic polarization of at least − 200 mV vs. O_2-equilibrium potential.

Catalysts for Anodic Hydrogen Oxidation. The mechanism of anodic hydrogen oxidation is much simpler than that of oxygen reduction. Reaction pathways would be revers of the Volmer – Heyrovsky or the Volmer – Tafel mechanism, i.e., with anodic adsorption (15 a)

$$H_2 \rightarrow H_{ad} + H^+ + e^- \quad (15a)$$

or dissociative chemisorption (15 b)

$$H_2 \leftrightharpoons 2\,H_{ad} \quad (15b)$$

as the initial steps.

Since the electrocatalysts must be stable under open-circuit conditions, the material of choice for alkaline fuel cells are Raney nickel [17], or carbon-supported Pt, Pd, and other platinum metals, and carbon-supported platinum, palladium, or alloys of platinum metals for fuel cells using acid electrolytes. Also tungsten carbide (WC) and platinized high-surface WC have been used succesfully in acid solution.

Properties, Preparation, and Improvement of Electrocatalysts in Gas Diffusion Electrodes.

Nanodisperse Platinum on Soot and Active Carbon. Because of their high internal surface, amounting typically to 100 m^2/g, soot and other active carbons are the most important catalyst supports for fuel cell electrodes. Platinum supported by active carbon is the fuel cell catalyst of choice for the cathode as well as for the anode.

Three different ways exist to dope the carbonaceous support material with platinum or other catalytically active noble metals.

1) Flooding of the active carbon by aqueous or organic solvents containing Pt salts with the help of wetting agents, drying of the flooded material and reduction of the deposited salts at low temperatures by hydrogen
2) Creating acidic groups (carboxylic acid and phenol groups) on the active surface by chemical oxidation with, e.g., chromic acid, fixation of cationic complexes of the catalyst (e.g., amino complexes of Pt(II) or Pt(IV)) at these groups by ion exchange, followed by chemical or electrochemical reduction of these complexes
3) Preparation of stabilized highly dispersed colloidal platinum in aqueous or nonaqueous solution by chemical reduction followed by adsorptive precipitation of the dispersed Pt particles on the surface of active carbon particles.

Ultimate goal of the catalyst preparation is to obtain very small platinum particles in order to increase the surface to volume ratio. Platinization by ion exchange and impregnation with colloidal platinum yield the best results in this respect [18].

Platinum Alloy Catalysts. By reaction of dispersed Pt on active carbon with metals of group 4 (IV B) and 5 (V B) dispersed alloys are formed which are very active electrocatalysts. Highly dispersed Pt – Cr or Pt – V alloys are formed by treating carbon impregnated with platinum and chromium or vanadium salts at 900 °C in an argon atmosphere.

Even after 9000 h of operation at 200 °C in 103 % phosphoric acid (H_3PO_4 polymer + P_2O_5) between 30 and 80 % of the nonnoble metal still can be found undissolved in the catalyst. This type of stabilized alloy catalyst is

used today in commercial fuel cell electrodes of phosphoric acid cells and contributes significantly to the technical success of this technology.

Due to catalyst aging phosphoric acid cells lose 18 % of their initial activity within 40 000 h. Two *aging mechanisms* for platinum-activated O_2 cathodes are discussed:

1) Anodic dissolution of Pt in the form of Pt(II) in off-times and diffusion of the dissolved species to the anode where Pt is deposited as metal or followed by reprecipitation of dissolved Pt in the cathode, which occurs if the cathode potential becomes more negative, results in coarsening of platinum particles.
2) Agglomeration of particles by stochastic movement on the soot particle of the supporting active carbon.

Anodic oxidation followed by dissolution of Pt and either reprecipitation or transfer to the cathode is the most important cause for deterioration. This aging mechanism is potential-dependent and accelerates as the cathode potential increases, for instance under partial load or in off-time, when the cathode potential drifts towards the oxygen equilibrium potential. Therefore, it is important that, whenever the cell is switched off, the oxygen in the cathode lumen is rapidly exchanged by inert nitrogen, and that the cell voltage under operation does not surmount 0.8 V.

Agglomeration of Pt crystallites due to Brownian motion can also be observed but is less effective. The interaction between the Pt particles and the supporting soot in presence of the electrolyte, phosphoric acid, is weak enough to allow for relatively free movement of the Pt particles. Alloy catalysts composed of platinum and non-noble metals show a reduced tendency to dissolution and agglomeration, thus their deterioration and activity loss is much slower than that of the pure platinum catalyst.

Silver Cathodes for Oxygen Reduction in Alkaline Electrolytes. Silver is one of the best electrocatalysts for cathodic oxygen reduction in alkaline solution. It is, however, readily oxidized to Ag_2O already at potentials of -200 mV vs. the oxygen equilibrium potential. In order to avoid anodic oxidation of silver followed by dissolution of the metal it is therefore essential, that in off-time the silver electrode is protected against anodic oxidation be cathodic polarization. Silver has been used successfully in alkaline fuel cells.

The silver is used in three different forms, namely as

1) Silver-doped carbon catalyst
2) Raney silver
3) PTFE-particles coated by a thin silver film in the form of Silflon cathodes

Whereas the literature on silver-doped carbon is relatively scarce more is known about Raney silver.

Raney silver – as is typical for Raney metals made from metals of relatively low melting point ($mp = 1000\,°C$) – is a much coarser material than Raney nickel ($mp = 1650\,°C$). It exhibits a specific surface of $\leq 1\,m^2/g$. The same holds for Silflon cathodes, which with silver loadings of $0.1\,g/cm^2$ of electrode area exhibit an active catalyst surface of no more than $\leq 0.24\,m^2/cm^2$ ($2.4\,m^2/g$). These Silflon electrodes are produced by chemically depositing silver on PTFE-particles of 0.5 to 1 µm size and working these silver-covered tiny particles into electrodes by calendaring or pressing. Figure 9 compares the current voltage curve of typical gas diffusion cathodes in an alkaline electrolyte. Evidently the Silflon electrode despite its relatively low active surface is superior even to the PTFE bonded Pt-activated active carbon electrode.

Figure 9. O_2 reduction current voltage curve in alkaline electrolyte at different cathodes
a) PTFE bonded active carbon, b) Pt-catalyzed active carbon, c) Silflon cathode

Particle Size and Utilization of Raney Nickel in Hydrogen Anodes. The particle sizes of Pt-activated soot (0.1 µm) and Raney nickel electrodes (several micrometers) differ by more than

an order of magnitude. It is the lower intrinsic catalytic activity of nickel compared to platinum in the hydrogen oxidation kinetics (j_0 (Ni) 10^{-6} A/cm^2 compared to j_0 (Pt) 10^{-3} A/cm^2) which permits to choose larger particles for gas diffusion anodes from Raney nickel than from Pt on active carbon.

Figure 10 depicts schematically the concentration profile of dissolved hydrogen in a porous catalyst particle brought about by competition of diffusive mass transport of hydrogen into the porous catalyst particles and the consumption of hydrogen by anodic oxidation at the inner surface of the catalyst.

Figure 10. Concentration distribution of dissolved hydrogen in a nanoporous anodic electrocatalyst particle. Depletion of H_2 in the particle results in decreased catalyst utilization

The utilization of the porous catalyst particle is given by the ratio of the actual current produced by anodic H_2 oxidation in the particle to the hypothetical current which would be produced in a spherical particle without mass transfer limitations

$$\eta = \text{utilization} = I/I_{\max} = 3\tanh\Phi_{\text{Th,el}}/\Phi_{\text{Th,el}} \quad (16)$$

According to the different exchange current densities j_0 for hydrogen oxidation and hydrogen evolution on Ni and Pt, the catalytic activity of platinum is by a factor of several hundred to thousand higher than that of nickel. Therefore, if the utilization of Raney nickel particles below 10 µm approaches 100 %, Pt-activated active carbon particles have to be smaller by a factor of 10 (square root of 100) to 30 (square root of 1000) than Raney nickel particles to achieve full utilization.

2.3. Ionic Conduction in Electrolytes

The ohmic potential drop ΔU_Ω (Eq. 17) is determined by the current density j, the electrode – electrode distance d, and the specific conductivity κ of the electrolyte solution:

$$\Delta U_\Omega = j d \kappa^{-1} \quad (17)$$

The specific conductivity κ of dilute electrolytes is the sum of the products of the equivalent conductivities λ_i, the charges n_i, and the concentrations c_i of the various ions that constitute the electrolyte solution.

$$\kappa = \sum_{i=1}^{m} c_i \lambda_i n_i$$

For electrolyte concentrations above ca. 10 mmol/dm^3, the simple linear relationship no longer holds because the λ_i become functions of concentration, typically diminishing with concentration. In general, electrical conductivities of aqueous electrolyte solutions increase with temperature because the viscosity, which determines ionic mobilities (Walde's rule, $\lambda_i \cdot \eta_i \approx$ constant),

decreases as temperature increases. But this rule fails dramatically for concentrated bases at temperatures exceeding 150 °C. This is demonstrated in Figure 11 for aqueous solutions of caustic potash of relatively high concentrations [19]. All curves for all concentrations show a maximum in specific conductivity at a temperature of ca. 150 °C although the viscosities of these solutions keep decreasing above this temperature. The reason for this phenomenon is likely a drastic change in the water structure. The progressive destruction of water clusters begins at ca. 150 °C.

The physical properties and conductivities of concentrated aqueous electrolyte solutions and of salt melts are quite comparable, as demonstrated in Table 1, so that the electrochemical engineer needs not take into account significantly altered electrolyte properties in switching from water to ionic melts.

Table 1. Specific and equivalent conductivities of sodium chloride in aqueous solution and in NaCl melts

Electrolyte	Temperature, °C	Conductivity, specific, $\Omega^{-1}\,cm^{-1}$	Conductivity, equivalent, $\Omega^{-1}\,cm^2\,mol^{-1}$
5.09 mol/dm^3			
NaCl (aq.)	18	2.13	42
NaCl (l)	802	3.58	117

Figure 11. The specific conductivity of aqueous potassium hydroxide solutions as functions of temperature [19]

2.4. Fluid Dynamics and Mass Transfer

In many liquids with viscosities comparable to that of water, most nonpolymeric species have diffusion coefficients of the order of $10^{-5}\,cm^2\,s^{-1}$. Therefore, convective diffusion is a relatively inefficient mass-transfer process in electrolytes, even under conditions of strongly forced convection. Figure 12 depicts the dependence of the mass-transfer coefficient k_m on the Reynolds number or equivalently, the flow velocity [20]. Even at Reynolds numbers of 10 000, in 1-cm-wide flow channels corresponding to flow velocities of 1 m/s, the mass-transfer coefficient does not exceed 10^{-2} cm/s.

Figure 12. Dependence of mass-transfer coefficient k_m on Reynolds number for the flow of aqueous solutions in a $1\times1\,cm^2$ channel [20]

The current density and the limiting current density are proportional to the mass-transfer coefficient and the driving concentration difference.

$$j = k_m z F \left(c^{x=\infty} - c^{x=0}\right)$$
$$j_l = k_m z F c^{x=\infty} \tag{18}$$

For a one-electron charge transfer and one molar solution, limiting current densities j_l of no more than 1 A/cm^2 may be obtained with $k_m = 10^{-2}$ cm/s, corresponding to a surface specific conversion rate of only $10^{-5}\,mol\,cm^{-2}s^{-1}$. This conversion rate (and the space – time yield) is low and therefore electrochemical reactors are relatively expensive. All available and reasonable technical means must be used in order to enhance mass transfer. Forced convection, gas sparging, and gas evolution at the counterelectrode in an undivided cell are effective methods to enhance mass transfer. Another is the use of so-called turbulence promoters in narrow-gap cells (see Section 3.5).

The dependence of mass-transfer coefficients on fluid dynamic conditions is best presented in dimensionless form, which is independent of the geometry of the electrolyzer and the actual properties of the solvent – solute system, especially the solvent viscosity and solute diffusivity. Therefore, rather than correlate the mass-transfer coefficient k_m with the linear flow velocity (forced convection) or with the Grashof number *Gr* (free convection), the Sherwood number *Sh* is correlated with the Reynolds number *Re*.

$Sh = k_m\, d/D$ — d = electrode – electrode distance; D = diffusion coefficient

$Re = u\, d/\nu$ — u = linear flow velocity; ν = kinematic viscosity

If expressed in terms of the mass-transfer-limited current density,

$$Sh = \frac{j_l}{z F c^{x=\infty}} \frac{d}{D}$$

such correlations must include the Schmidt number, $Sc = \nu/D$, which accounts for the viscosity and diffusivity of a particular solvent – solute system.

Many industrial electrolyzers work under forced convection or under gas stirring. Free convection is important in metal refining and metal electrowinning. Table 2 summarizes important dimensionless correlations involving mass transport for free and forced convection for various types of electrode arrangements [21]. The most important for electrochemical engineering are certainly the correlations for the parallel plate cell with forced convection under laminar and turbulent conditions.

3. Electrochemical Cells

The parallel plate cell, undivided or divided by a diaphragm or a membrane, is the classical cell geometry for industrial electrolyzers. Such a parallel plate cell may constitute an entity on its own, and is operated in the *monopolar mode.* Several parallel plate cells may be put in series into a filter-press-like setup and are operated in the *bipolar mode* – each electrode operating as an anode on one side and as a cathode on the other side. Apart from the current-density distributions, the monopolar – bipolar options do not differ with respect to fluid dynamics and other operational characteristics and there is, in principle, no preference for either of these modes.

Construction of the bipolar electrolyzers is generally simpler than for monopolar electrolyzers, but material and corrosion problems are generally easier to solve in monopolar electrolyzers because stack shunting and stray currents are not encountered. Anode and cathode often are made of different metals (e.g., chlor-alkali cells have titanium anodes and steel or nickel cathodes), and generally different materials are not easily combined into one bipolar plate. Moreover, in bipolar electrolyzers all electrolysis cells are connected to each other by the electrolyte manifold, which supplies the cells with the circulated electrolyte. This electrolytic connection acts as an electrical shunt, which induces uneven current distributions along the stack. The highest current densities occur in the cells at the ends of the stack. The consequence is that effective current efficiencies decrease and energy consumption increases as the number of cells in the stack increases. If the current is interrupted, the cells in series act as galvanic cells, which can lead to reverse electrolysis, at least in some cells, possibly severely corroding and damaging these reversed cells.

Figure 13. Schematic presentation of cell voltage (heavy line) versus current density
Cell voltage consists of decomposition voltage $U_{0,c}$, ohmic potential drop ΔU_Ω, anodic overpotential η_a, and cathodic overpotential η_c.

Because of these difficulties, bipolar electrolyzers have been developed up to commercial maturity only in a limited number of cases. In these cases the anode and the cathode material have usually been the same, and corrosion and destruction due to current reversal is of little importance due to insensitivity of the electrodes to reversed operation. These cases include alkaline water electrolysis with bipolar steel or nickel electrodes and electrolysis of hydrochloric acid with bipolar carbon electrodes. The construction problems have also been overcome for bipolar chlor-alkali electrolyzers.

Table 2. Dimensionless correlations involving mass transfer [21]

System	Correlation ∗	Characteristic length and velocity used for definition of dimensionless quantities	Validity limits ∗
Forced convection along parallel plate cell	1) $Sh = 2.54\ (ReSc)^{1/3}\ (d/L)^{1/3}$	electrode gap and length	1) $Re \leq 3000$, laminar flow
	2) $Sh = 0.025 Re^{0.8} Sc^{1/3}$		2) $Re > 3000$, turbulent flow
Free convection along vertical plate, laminar flow	$Sh = 0.66\ (ScGr)^{1/4}$	height of electrode	$500 < Sc < 80000$ $10^4 < Gr < 10^9$ $5 \times 10^6 < ScGr < 5 \times 10^{12}$
turbulent flow	$Sh = 0.31\ (ScGr)^{0.28}$	height of electrode	$4 \times 10^{13} < ScGr < 10^{15}$
Free convection across horizontal plate	$Sh = 0.19\ (ScGr)^{1/3}$	length of electrode	$10^8 < ScGr < 1.4 \times 10^{12}$ $2.1 \times 10^3 < Sc < 5.2 \times 10^4$
Free convection between vertical electrode and diaphragm	$Sh = 0.0225\ (ScGr)^{0.85}\ (e/h)^2$	electrode – diaphragm distance e	$2 \times 10^6 < ScGr < 2 \times 10^8$ $0.005 < e/h < 5.48\ (ScGr)^{-0.3}$
Flow along plate	$Sh = 0.66 Re^{1/2} Sc^{1/3}$	height of electrode in flow direction, linear flow velocity	$Re < 3 \times 10^5 - 10^6$
Axial flow through gap between two coaxial cylinders,		equivalent diameter, flow velocity	$300 < Sc < 3000$
laminar	$Sh = 1.62\ (ReSc)^{1/3} \left(\frac{d_e}{L}\right)^{1/3}$		$300 < Re < 2100$
turbulent	$Sh = 0.023 Re^{0.8} Sc^{1/3}$		$2100 < Re < 30000$
Rotating cylinder	$Sh = 0.079 Sc^{0.356} Re^{0.7}$	diameter of cylinder, circumferential velocity	$1000 < Re < 100000$ $835 < Sc < 11490$
Rotating cylinder with coaxial stationary hollow cylinder	$Sh = 0.079 Re^{0.7} Sc^{0.356}\ (d_2/d_1)^{0.7}$	diameter of counter-electrode, circumferential velocity	$1000 < Re < 53000$ $0.22 < d_2/d_1 < 0.68$

∗ Sh = Sherwood number = $j_l\ L/Dc^{x=\infty}$; Gr = Grashof number = $g\ L^3\ (\varrho_0 - \varrho_e)/\varrho_0\ \nu^2$; Re = Reynolds number = ud/ν; Sc = Schmidt number = ν/D ;
d = electrode gap; d_1 = diameter of stationary working electrode; d_2 = diameter of rotating counterelectrode; d_e = equivalent diameter = $(d_2 - d_1)$; e = diaphragm – electrode distance; h = height of electrode; L = electrode length

The engineering of single cells – irrespective of their incorporation into a bipolar stack or their monopolar operation – must incorporate a constructional design and mode of fluid dynamic operation that takes into account several phenomena, all of which might interfere with cell operation by increasing overpotentials and ohmic potential drops.

The most important of these phenomena are (1) uneven current distribution, which partially increases local current densities above mean current density, thus increasing the overpotential, (2) increase of the specific resistivity of the electrolyte by incorporation of dispersed gas bubbles, which can even partially block the electrodes by formation of gas blankets, and (3) excessive electrode distance or an inappropriate diaphragm or membrane with excessive electrical resistance. Figure 13 underlines the importance of these factors by presentation of the cell voltage of a water electrolyzer as a function of current density. For a low current density, increases in cell voltage are caused mainly by the increase of overpotential. For a high current density, it is to a large extent the internal resistance, ΔU_Ω, that determines the further increase of cell voltage with current density [22].

3.1. Optimized Current Density

The type of cell voltage – cell current density correlation in Figure 13 permits the use of a linear approximation for U_c vs. j in the domain of

higher current densities, which are the ones of commercial concern

$$U_{\text{cell}} = U_c^* + jR^*$$

where $U*_c$ is the apparent decomposition potential and $R*$ is the effective surface specific resistance of the cell ($\Omega\,\text{cm}^2$, also called the k-value).

The cell voltage, and hence energy consumption per unit mass of product, increases linearly with current density. Since for a fixed production per unit time the electrode area (or number of electrolyzers) varies inversely with current density, the investment costs are proportional to j^{-1}. Total specific product costs equal energy costs plus investment costs, in symbols:

$$C = Aj + B/\text{j}$$

C = total costs per unit mass of product
A = energy cost coefficient, mainly determined by effective cell resistance $R*$
B = investment cost coefficent

As illustrated in Figure 14, according to this approximation there is an optimal current density, which determines the lowest production costs and which depends on energy price.

$$j_{\text{optimal}} = \left(\frac{B}{A}\right)^{1/2}$$

High energy prices call for low current densities, whereas low energy prices allow the process to be designed to run with high current densities [22].

Figure 14. Total specific product costs versus current density (schematic)

3.2. Primary, Secondary, and Tertiary Current Distributions

The current distribution between any two parallel electrode surfaces is only uniform in cases where a nonconducting containment of the same cross section surrounds the interelectrode space. In all other cases, the current density is unevenly distributed, leading to higher current densities at the edge of the electrodes. If the electrode is not smooth, current densities are also enhanced on whiskers, steps, or studs that protrude from the electrode into the electrolyte toward the other electrode. Neglecting any polarization effects, in particular neglecting the dependence of current density on overpotential (Butler – Volmer equation, Eq. 2), permits calculation of the *primary current-density distribution* according to the Poisson equation, a fundamental principle of electrostatics. The primary current-density distribution neglects charge transfer kinetics.

However, the exponential dependence of current density on overpotential and the linear dependence of ohmic voltage drops on current density (Eq. 17) causes a notable smoothing and equalization, the *secondary current-density distribution*, which prevails whenever actual current densities everywhere at the electrode surface are much lower than mass-transfer-limited current densities ($j < 0.1\,j_l$): the secondary current-density distribution neglects mass transfer. Figure 15 depicts schematically the primary and secondary current-density distribution at a plane electrode. Wagner showed that geometric similarity can be applied to current density distributions of electrodes of similar form but different size whenever the Wagner number *Wa* is equal for two different electrodes or electrolysis cells.

$$Wa = \kappa \left(\frac{\text{d}U}{\text{d}j}\right) / d$$

$\frac{\text{d}U}{\text{d}j}$ = polarization resistance
d = characteristic length

The higher the Wagner number, the more uniform the current density distribution. Whenever mass-transfer limitations prevail ($j \approx j_l$), the secondary current-density distribution is outweighed by the current-density distribution as dictated mainly by the progressive depletion of

the depolarizer, which then defines the *tertiary current-density distribution* ($j = j\,(c^{x=\infty})$,

Eq. 18): the tertiary current distribution is observed for mass transfer-controlled currents and does not resemble the primary and secondary current distributions at all. Instead, it reflects only the locally variable mass-transfer rate of the particular electrode at the particular convective-diffusion or nonsteady diffusive mass-transfer conditions.

Figure 15. Primary, secondary, and tertiary current-density distribution for an electrolyte flowing between parallel electrodes
j_x/j_m = local current density/mean current density

Figure 16 shows some cases where tertiary current-density distributions are important whenever electrolyte solutions contain the depolarizer in low concentrations ($c < 10^{-2}$ mol/dm^3). A typical case is the current distribution in porous or packed-bed electrodes used for wastewater treatment (Fig. 16B) to extract noxious metal ions such as Cu^{2+} from galvanic effluents (see Section 4.6).

Figure 16. Schematic presentation of the primary and tertiary current-density distributions at (A) the rotating disk electrode and of tertiary current-density distribution in (B) a packed-bed electrode with (a) counterelectrode and (b) feeder electrode
Tertiary current density distribution is depicted for mass-transfer-controlled current densities in both cases.

3.3. Gas-Evolving Electrodes

Most of the important industrial electrochemical processes are accompanied by gas evolution, either at one electrode or both. The existence of a gas phase adhering to an electrode or in the electrolyte bulk significantly complicates operation of electrochemical reactors. Whenever gas bubbles form at an electrode, they interfere with the electrochemical and physical events. The interference is not restricted to the electrode surface or an adjacent electrolyte layer, but spreads throughout the whole interelectrode gap. To ensure optimal operation of these electrochemical reactors requires an understanding of the causes and effects of the manifold phenomena associated with gas evolution [23, 24, 25, 26].

The gas does not form at the electrode as an immediate consequence of an electrode reaction. The substance is formed on the electrode-electrolyte interface and appears first dissolved in the solution. For this reason, the highest concentration of dissolved gas occurs at this interface, and the concentration polarization caused by this may significantly increase the cell voltage.

When the interfacial concentration of dissolved gas exceeds a certain value, stable gas bubbles start to grow at nucleation sites, i.e., preexisting gas residues trapped in pits, scratches, and grooves on the electrode surface. The bubbles grow from the supply of dissolved gas in the supersaturated electrolyte and induce microconvection, which in turn increases the mass-transfer rate of dissolved gas and thus increases the bubble growth rate. Simultaneously, microconvection affects mass transfer of any substance to or from the electrode, e.g., species of the main reaction. Therefore, electrodes covered with growing bubbles exhibit mass-transfer behavior significantly different from that of bubble-free electrodes.

The microevents at the electrode are stochastic in space and time. For this reason, and unlike the situation for electrodes without gas evolution, the current density can be considerably different at points close to one another and at the same time vary at one point extremely quickly. Measured values are commonly average values.

When the bubbles detach from the electrode, tehy rise in the electrolyte, imparting momentum to it. Electrolyte flow past the electrode develops. Depending on the type of industrial electrochemical reactor, this flow may be sufficient to obviate the need for a pump. This effect is most pronounced in interelectrode gaps between vertical electrodes, but by skillful design of the flow channels it can also be utilized with horizontal electrodes. Violent macroflow of the electrolyte contributes significantly to mass transfer.

Another aspect of the effects of gas evolution results from the fact that bubbles adhering to the electrode partly shield the electrode surface and thus diminish its effective area. The shielding of the electrode results in an increase of the local current density and consequently increases the local overpotential. Gas evolution is seen to have two antagonistic effects on mass transfer: adhering gas bubbles interfere with mass transfer by decreasing the available electrode area, while their growth and departure from the electrode enhances convective mass transfer.

After detachment from the electrode, the bubbles remain for some time in the interelectrode gap where they increase the effective resistivity of the electrolyte. Since an increasing fraction of the dispersion consists of gas bubbles as the dispersion flows through the cell, the current distribution is nonuniform.

Regimes in Gas Evolution. Whether the substance generated at the electrode is transferred into the gas phase or stays dissolved depends on the conditions. For low current densities, the concentration gradient at the electrode – electrolyte interface is large enough to transfer the generated molecules dissolved to the bulk electrolyte by convective diffusion. The interfacial concentration of dissolved gas is too low to activate nucleation sites at the electrode surface, and gas bubbles are not formed. Increasing the current density increases the interfacial concentration of dissolved gas to such an extent that nucleation sites located on the electrode surface are activated. Stable bubbles form and grow by diffusion of dissolved gas from the surrounding supersaturated electrolyte. When the bubble attains a sufficient size, it detaches from the electrode. After a time, a new bubble forms at the same nucleation site, and the cycle restarts.

An important anomaly is coalescence of bubbles on the electrode surface, which may occur within 10^{-4} s when bubbles touch. A peculiar

phenomenon is the jump-off upon coalescence of two bubbles of nearly equal size, characterized by a departure of the united bubble from the electrode, followed by an immediate return to the electrode, where this bubble remains attached for some time [27]. Another type of bubble coalescence is the sliding of large bubbles upward along vertical electrodes while incorporating small bubbles. Coalescence also occurs after departure of bubbles from the electrode. Departing bubbles induce a wake flow that makes smaller bubbles slip across the electrode surface [28]. Under conditions that are not fully understood, tiny bubbles can be rapidly ejected from the electrode [29], [30]. These irregularities greatly complicate reliable predictions of the behavior of gas-evolving electrodes.

Large current densities, with associated high gas evolution rates, increase the number of active nucleation sites on the electrode surface and favor coalescence of bubbles at the electrode surface. A more or less extended gas film forms, initially covering discrete areas of the electrode, but which can finally cover almost the complete electrode area, interrupting the current. In the Hall-Héroult process for aluminum, this is known as the anode effect.

Rate of Gas Evolution. Figure 17 shows an overview of possible paths of hydrogen between electrochemical generation and the gas phase. After desorption from the electrode surface, the hydrogen may dissolve partly in the electrode material, partly in the electrolyte, and diffuse in both directions.

The hydrogen may partly be trapped in the electrode material (5), partly permeate through the electrode (6), or enter an adhering bubble by crossing the metal – gas interface (7). For most electrode materials these three paths are unimportant; however, they may be relevant for metals possessing high hydrogen solubility, such as palladium and some of its alloys.

Usually, almost all of the generated hydrogen dissolves in the electrolyte. The supersaturation of the electrolyte with gas at the electrode – electrolyte interface causes hydrogen to diffuse partly to bubbles adhering to the electrode, where it enters the gas phase (8), and partly to the electrolyte bulk where it may be incorporated into freely moving bubbles (9), or hydrogen may leave the interelectrode gap still in solution (10).

The fraction attributable to each depends on the operational conditions, the material and state of the electrode, and the kind of electrolyte, and may differ significantly from case to case. Usually path 8 is considered to be dominant, and the rate of gas evolution can be directly calculated from Faraday's law. However, for many cases this is an inadmissible simplification. Generally, only a fraction of the product generated is transferred to bubbles adhering to the electrode. This fraction, the gas evolution efficiency, is small for low current densities and continues to be markedly lower than unity for the current densities used for most industrial processes (500 – 10 000 A/m^2) [31, 32, 33, 34, 35].

The rate of gas evolution is even lower when the electrolysis product reacts either with the electrode (1, 2) or with the electrolyte (3, 4), e.g., in the production of hypochlorite, where no gaseous chlorine evolves.

Mass Transfer at Gas Evolving Electrodes. Gas bubbles are already formed at electrodes above very low values of the current density (about 1 A/m^2) and are generally able to affect mass transfer of any dissolved species. However, below about 1000 A/m^2, the effect of forced convection and/or single-phase natural convection usually predominates although gas bubbles are present at the electrode. Forced convective mass transfer may be estimated from well-known mass transfer equations. Single-phase free convective mass transfer is affected by concentration gradients rather than by temperature gradients [36]. An equation particularly adapted to the conditions of gas evolving electrodes is available [37].

Conditions change significantly as the current density is raised above about 1000 A/m^2. Not only the number of bubbles adhering to the electrode increases substantially as the current density is increased, but also their growth and thus the frequency of detachment from the electrode increases. Rapidly growing and detaching bubbles affect the mass transfer by vigorously stirring the boundary layer. The superimposed bubble-induced mass transfer becomes strong enough to govern overall mass transfer at large current densities. The action of bubble-induced mass transfer is rather complex and depends on

Figure 17. Schematic overview of the paths of hydrogen formed at an electrode
The various paths (1 – 10) are described in the text.

the pressure and temperature of the electrolyte; the rate of gas evolution (a function of the current density); and position, polarity, and surface of the electrode. Various models have been developed for bubble-induced mass transfer, each considering particular effects to be dominating [24].

In the *penetration model* [42], the core concept is that a bubble departing from the electrode induces a wake flow, which provides replacement of the boundary layer and cyclic penetration of fresh electrolyte to the electrode. The resulting equation is

$$Sh = \frac{2.76}{C}\,(ReSc)^{0.5}\,(1-\theta)^{0.5}$$

The dimensionless groups are

Sherwood number	$Sh = \frac{k_2 d_b}{D}$
Reynolds number	$Re = \frac{u_G^* d_b}{\nu}$
Schmidt number	$Sc = \frac{\nu}{D}$

The geometry of the adhering bubble is taken into account by the value of C, e.g., $C = 1.59$ for a hemispherical bubble and $C = 2$ for a spherical bubble. The parameter θ denotes the fraction of the electrode surface shielded by adhering bubbles [42], [43]. The Reynolds number is formed with the volume flow density u_G* of gas evolved at the electrode. The mean diameter of bubbles departing from the electrode d_b is of the order of 50 µm in aqueous electrolytes, although it can differ from this substantially, especially in molten salts [26].

The *microconvection model* takes account of the growth of bubbles adhering to the electrode surface. Growth pushes electrolyte over the electrode in a radial direction. A microconvective flow regime develops in the vicinity of the bubble. The resulting equation [44]

$$Sh = 1.89\,\left(Re^{0.5}\,Sc\right)^{0.487} \cdot \left[\theta^{0.5}\,\left(1-\theta^{0.5}\right)\right]^{0.5}$$

can be approximated in the range of mean current density values ($0.15 < \theta < 0.4$) by

$$Sh = 0.93 Re^{0.5} Sc^{0.487}$$

which exhibits fair agreement with experimental data.

The *hydrodynamic model* considers the flow of bubbles after detachment from the electrode as the predominant effect on mass transfer [45]. Adhering bubbles are disregarded. The fundamentals of the model have been discussed [24], but practical application is more problematic than for the other models. A promising attempt was made to develop a combined convection–penetration model [46].

The combined action of various mass transfer mechanisms, separately calculated for the mass transfer coefficients k_1, k_2, and k_3 may be roughly estimated from [38]:

$$k = \left(k_1^2 + k_2^2 + k_3^2\right)^{0.5}$$

The vector addition of the coefficients gives fair correlation with experimental results [39], [40] and has been confirmed theoretically [41].

Heat Transfer. The overtemperature of gas-evolving electrodes was long considered to be quite high. However, investigations have shown that the surface temperature of electrodes operating properly is only a few degrees above the electrolyte bulk temperature. Whenever an estimate of the electrode surface temperature is required, the bubble-induced rate of heat transfer may be estimated from [47]:

$$Nu = 0.93 Re^{0.5} Pr^{0.487}$$

where the additional dimensionless groups are

Nusselt number	$Nu = \frac{h\, d_b}{\lambda}$
Prandtl number	$Pr = \frac{\eta\, c_p}{\lambda}$

where h is the heat-transfer coefficient, λ is the thermal conductivity, η is the dynamic viscosity, and c_p is the specific heat capacity at constant pressure.

Electric Conductivity of Gas–Electrolyte Dispersions. The effective electric conductivity of gas–electrolyte dispersions may be substantially smaller than the conductivity of the bubble-free electrolyte. The conductivity is correlated to the volume fraction v of the gas in the dispersion (void fraction) and in an electrolyzer generally varies in the direction perpendicular to the electrode surface as well as in the main flow direction of the electrolyte. The effective conductivity depends not only on cell geometry, but also on the flow rates of evolved gas and the electrolyte.

The problem of the effective conductivity of a dispersion with uniformly distributed gas bubbles was first treated more than 100 years ago. There are numerous theoretical and some empirical equations for the effective conductivity κ of a dispersion relative to the conductivity κ_L of bubble-free electrolyte. The most important equations are those derived by Maxwell [48] and Rayleigh [49]

$$\frac{\kappa}{\kappa_L} = \frac{1-v}{1+v/2} = \left(1 + 1.5\frac{v}{1-v}\right)^{-1}$$

by Bruggeman [50]

$$\frac{\kappa}{\kappa_L} = (1-v)^{1.5}$$

and by Prager [51]

$$\frac{\kappa}{\kappa_L} = (1-v)\,(1 - v/2)$$

Series expansion shows that all three equations coincide for $v \to 0$. Further equations have been reviewed [26]. Which of these equations is the most satisfactory one is difficult to decide since their deviation for usual values of v are smaller than the scatter of experimental data and small enough to make each of the equations useful in practice.

The major practical problem is the assessment of v under real conditions. In most cases electrolyte flow is forced in industrial cells. Large electrolyte velocities are an efficient means to keep the gas fraction low.

The absolute velocity of gas bubbles in a swarm depends on the volume flow rates of gas and liquid, $\dot{V}_G$ and $\dot{V}_L$, and on the cross section S.

$$u_G = \frac{\dot{V}_G}{Sv} = \frac{\dot{V}_L}{S\,(1-v)} + \frac{u_{rs}}{1-v} \tag{19}$$

The last term represents the relative rising velocity of both phases considered as continua [52]. The rising velocity u_{rs} of a bubble swarm depends on the rising velocity u_r of a single bubble of diameter d_b in vastly extended stationary liquid,

$$u_r = \frac{g d_b^2}{C\nu}$$

and on void fraction v according to

$$u_{\mathrm{rs}} = u_{\mathrm{r}}\,(1-v)^n$$

where $n = 4.5 - 4.65$ [53], [54] and the values of C are 18 for a rigid bubble surface and 12 for a mobile one, particularly depending on the presence of surface-active substances in the electrolyte [55]. Equation (19) is accurate for large values of the ratio $\dot{V}_{\mathrm{L}}/\dot{V}_{\mathrm{G}}$ only, but fails for stationary electrolyte, $\dot{V}_{\mathrm{L}} = 0$, since it allows values of v equal to or near unity, which are unrealistic in bubble – electrolyte dispersions. Various modifications of Equation (19) to extend its range are available [56], [57].

If the gas fraction v of the dispersion flowing between planar electrodes is approximately considered constant in the direction perpendicular to the main flow direction, the mean relative conductivity of the dispersion is

$$\frac{\kappa}{\kappa_{\mathrm{L}}} = 1 + 0.75\frac{\dot{V}_{\mathrm{Gt}}}{\dot{V}_{\mathrm{L}} + u_{\mathrm{rs}}\,(1-v)^n\,S}$$

where $\dot{V}_{\mathrm{Gt}}$ denotes the total gas flow rate at exit of the interelectrode gap [58, 59, 60, 61, 62]. Neglecting the effect of the relative velocity u_{rs}, i.e., setting the slip ratio

$$\sigma = \frac{\dot{V}_{\mathrm{G}}}{\dot{V}_{\mathrm{L}}}\,\frac{1-v}{v} = 1 + \frac{u_{\mathrm{rs}}}{\dot{V}_{\mathrm{L}}/S}$$

approximately equal to unity [63], yields the simple, practical equation [64]

$$\frac{\kappa}{\kappa_{\mathrm{L}}} = 1 + 0.75\dot{V}_{\mathrm{Gt}}/\dot{V}_{\mathrm{L}}$$

Frequently, an older stagnant-electrolyte model [65] is used to assess the ohmic voltage drop, but such a model may involve heavy deviations from reality for all cases with forced flow.

The assumption of uniform bubble distribution in each area perpendicular to the main flow direction is applicable to the bulk of flowing dispersion, but fails for the nearly stagnant bubble layer close to the electrode, where bubbles are crowded. The assessment of this stagnant bubble layer resistance has been the object of several investigations [66, 67, 68]. Models taking account of the resistance of a stagnant layer together with the resistivity of the flowing central part are available [69, 70, 71].

Increasing the interelectrode distance of gas-evolving electrochemical reactors lowers the frictional pressure drop of the dispersion, and provides an optimization problem with respect to the voltage drop. Various systems with natural and with forced electrolyte circulation were studied with regard to the energy requirements of the total hydraulic system of electrolyte inside and outside the cell [72, 73, 74, 75, 76].

All these models refer to planar, nonperforated electrodes. For perforated electrodes, adequate models are not yet available.

3.4. Cells with Two-Dimensional Electrodes

The simplest electrode shapes are the plate and the cylinder. Owing to their generally low production costs, they have been used frequently and on an industrial scale. Due to increasing demands in economy and maintenance of industrial processes, electrodes of various special shapes have been introduced into industrial practice to an increasing degree. The perforated plate, extended metal, slitted, grooved, louvered, or other regularly deformed electrode surfaces do not really increase the geometric surface of the electrode. These electrodes are active on their outer surface only and are often termal two-dimensional to distinguish their action from that of the three-dimensional electrodes (see Section 3.6.).

Vertical Electrodes. Beginning many decades ago the form of vertical planar electrodes was modified by holes or slits [77], the action of which seems to have not always been fully understood. On one hand, the effective electrode area is diminished, but on the other hand, there is a gain in surface area due to accessibility of the rear side and the inner edges, although these are positioned at a greater distance from the counterelectrode. These modifications are advantageous in all cases of gas evolution at the electrode because release of bubbles at the rear side of the electrode is facilitated. As shown by experiment [78], the gas – electrolyte dispersion flows through the holes of a planar electrode – except for a rather short zone at the entrance side – and leaves the interelectrode gap (Fig. 18). Thus the effective ohmic resistance of the dispersion is reduced significantly. Attention must be paid to the size of the holes in

the electrode because holes too small, although desirable with respect to uniformity of current distribution, can result in gas bubble trapping [79], [80].

Figure 18. Flow pattern in a cell with vertical perforated electrodes [78]

Figure 19. Gas-diverting electrodes
A) Expanded metal electrode; B) Louvered electrode [84], [86]

Unflattened expanded metal gauze electrodes and electrodes fitted with louvers or slots (Fig. 19) are especially effective as electrodes favoring the release of gas – electrolyte dispersion to the rear of the electrode [81, 82, 83, 84, 85]. Mesh electrodes provided with inclined ramps at regular intervals or louvered mesh electrodes serve the same purpose. The inclination angle of the fins has an optimum value [87].

However, gas diversion to the rear side of the electrode can make the design of the electrochemical reactor as a whole problematic. In cells with central monopolar (unipolar) electrodes, where gas evolution occurs equally at the front and rear sides, gas removal through the electrode is not feasible, and in cells with bipolar electrodes, the catholyte and anolyte compartments on opposite sides of the electrode ordinarily are separated hydraulically. In these two cases gas-diverting preelectrodes, which are electrochemically active and at the same time separate the interelectrode gap from a chamber where the gas – electrolyte dispersion is collected without unduely increasing the interelectrode resistance, are a possibility (Fig. 20). The dispersion essentially flows parallel to the electrodes through the rear chamber; the interelectrode distance between preelectrode and counterelectrode can be kept small. However, the use of preelectrodes conflicts with the need for compact cell design and often leads to bulky electrochemical reactors.

Figure 20. Preelectrode
A) Monopolar; B) Bipolar

Horizontal Electrodes. In the case of horizontal electrodes facing downwards, a design producing effective gas release usually gets highest priority, since gas bubbles can accumulate easily and coalesce to form abnormally large

bubbles or extended gas films, which insulate the electrode at least partially [88], [89]. An effective remedial measure is to impart a large velocity to the electrolyte removing the gas. However, this cannot be done in all processes.

Special problems are encountered in the electrolysis of alumina (Hall – Héroult process), where carbon anodes of considerable cross section are immersed from above into the molten cryolite electrolyte. Owing to the continuous combustion corrosion of these anodes inherent in the process, there is no possibility of shaping the electrode with a geometry that allows fast gas removal and that at the same time is sufficiently durable. The active surface of this electrode is essentially planar. The problem has encouraged extensive research, the outcome of which is more related to the extent of the shielding effect than to corrective measures. A gas bubble layer of considerable thickness is formed even in medium-sized electrode areas [90], [91]. However, a small inclination of the electrode surface from the horizontal induces a flow of gas – electrolyte dispersion that removes the gas safely [92]. Angles as small as 1° seem to be sufficient [89]. This possibility has scarcely been used systematically in the aluminum industry so far because of the shape instability of the carbon anodes.

In other cases, the most common way to ensure gas removal is the use of specially shaped surfaces. This technique has long been used on an industrial scale. Grooves in the electrode surface accumulate gas bubbles, which are removed by vigorous electrolyte flow. Of course, this electrode design causes a loss in active electrode area, as compared to planar surfaces, often resulting in considerable increase in effective current density and overpotential. However, this effect is more than offset by the beneficial action of smooth gas removal and can be especially advantageous for small interelectrode widths. The grooves are usually oriented parallel to the main flow direction, or if necessary are widened to balance the increasing gas volume transported [93]. With appropriate connecting vertical flow channels, the electrolyte flow is sufficient to dispense with any mechanical pump [94].

Wherever possible, vertical holes are used. This measure is easily able to prevent excessive accumulation of gas below the electrode. A typical example was the graphite anode that was used up to a decade ago in the chlor-alkali mercury process [95], [96]. The introduction of solid metal electrodes allowed the perforated graphite electrodes to be replaced by nets, expanded metal gauze, or parallel wires or rods, which allow the efficient release of chlorine [97], [98].

In special cases, e.g., in the electrochemical production of permanganate or in anodic oxidation of wastewaters, it is expedient to operate anode and cathode with distinctly different current densities. Instead of partially covering one of the electrodes [99], the electrode can be formed from a base plate covered by numerous layers of nets electrically connected with the base plate and thus active as the anode [100].

Microporous Electrodes. Fuel cell technology has shown that gases evolved at both electrodes of a cell can be separated without the use of a diaphragm if microporous electrodes are used. These electrodes were originally developed to meet the requirements of a stable gas – liquid – solid interface, but were found also to have favorable characteristics as gas-evolving electrodes. One of these is the so-called *valve electrode*, which is composed of two layers of markedly different porosity, each homoporous in itself (Fig. 21A). One layer, which is electrocatalytically inactive and in contact with the electrolyte, allows the electrolyte access to the other layer, which is electrocatalytically active and where gas is evolved. Because of its finer porosity, the first layer is permanently filled with electrolyte, and the gas formed can only be released on the rear of the electrode, which has the coarser porosity [101]. Major industrial importance is expected for another type of porous electrode, the *double-skeleton electrode* (Fig. 21B). Unlike the system just described, it utilizes a diaphragm. The electrode consists of a single porous layer that, however, incorporates two mutually piercing pore systems of different porosity. If the pressure difference between electrolyte and gas compartment is appropriately adjusted, the fine pore system in the electrode is filled with electrolyte, while the coarser one is not and serves for gas release. The concept dispenses with separate gas channels inside the cell block and allows compact design, which also does not require separate electrolyte compartments [102], [103]. To avoid mass-transport problems,

these electrodes must be thin. With respect to geometry, therefore, these electrodes are classified as two-dimensional, while operationally they form the transition to the three-dimensional electrodes.

3.5. Special Cell Designs

During the past two decades, many specialized electrochemical cells have been designed. For example, the electrolytes used in organic electrochemistry often have conductivities much lower than those of aqueous solutions; therefore, the ohmic voltage drop constitutes a considerable part of the total cell voltage, thus resulting in high specific energy consumption [104].

A suitable cell design is required to offer a low ohmic voltage drop even with poorly conducting electrolytes. This objective can be achieved by minimization of the interelectrode gap. For the economics of an electrochemical process not only is the specific energy consumption important, but also the space – time yield [104],

$$STY = a_e \frac{j M_r \phi^e}{z F} \tag{20}$$

The space – time yield is proportional to the specific investment cost, which is the product of a design factor (the specific electrode area a_e) and a reaction factor (current density and current efficiency).

In many electroorganic reactions (see Chap. 5) and in the electrochemical deposition of metals from wastewaters (see Chap. 4.6), the current density is limited either by slow reaction or by diffusion. In such cases, improvement of the space – time yield requires a cell design incorporating large specific electrode area.

In Figure 22, the specific electrode area of various electrochemical cells is shown as a function of characteristic length (interelectrode distance or particle diameter); it is seen that available electrochemical cells differ in specific electrode area and characteristic length by orders of magnitude. As can be seen from Equation (20), for a current efficiency of 1 the space – time yield is determined by the product $a_e j$

$$a_e j = \frac{I}{V} = j^*$$

The quantity $j*$, in units of A/cm^3, is sometimes referred to as current concentration. This quantity is shown in Figure 23 as a function of the characteristic length. To estimate these $a_e j$ values, typical current densities for known applications of these cells were chosen. Extremely high current densities, e.g., 10 kA/m^2 in the chlor-alkali electrolysis, can be applied only in a limited number of cases, and the use of cells with high specific electrode area is restricted to cases of low current densities.

The special cell concepts are listed in Table 3, where each cell design is qualitatively characterized with respect to ohmic voltage drop, mass-transfer rate, and specific electrode area.

In the classical parallel-plate cells, which are usually applied as filter-press-type arrangements, *turbulence promoters* [3], [105], [106] can be introduced easily into the interelectrode

Figure 22. Specific electrode area as a function of characteristic length for various electrochemical cells

Figure 23. Typical current concentrations as a function of characteristic length for various electrochemical cells

gap or into the diaphragm – electrode gap to enhance mass-transfer rate. In Figure 24 a schematic view of such a cell is shown, with rods acting as turbulence promoters mounted between the electrodes of a parallel-plate cell, their axes perpendicular to the electrolyte flow. For channel flow, the regime changes from laminar to turbulent at a critical Reynolds number of ca. 2300. This critical Reynolds number is drastically decreased by the turbulence promoters, so that a higher mass-transfer coefficient providing a higher space – time yield, is achieved, at lower flow rates. A further advantage of turbulence promoters is the independence of the flow length and the diffusion layer thickness and thus the diffusion-limited current density. For laminar flow at a plate electrode within a channel, the integral mean diffusion-limited current density is [107]

$$j_l = 2.45 z F D^{2/3} L^{-1/3} d_e^{-1/3} u^{1/3} c_0$$

i.e., current density decreases as electrode length increases. This effect, which limits the extension of the electrode, does not occur under turbulent conditions, where the local current density is site-independent. Instead of rods, plastic tissues or nonconducting particles in the form of a packed or fluidized bed may also serve as turbulence promoters.

Table 3. Modern concepts of cell design

Cell	Ohmic voltage drop	Mass transfer rate	Specific electrode area
Cells with turbulence promoters	high	high	small
Rotating cylinder electrode cell	high	high	small
Trickle tower cell	high	high	large
Capillary gap cell	low	low	small
Pump cell	low	high	small
Swiss-roll cell	low	high	large
Zero-gap cell	low	low	small
Solid polymer electrolyte cell	low	low	small

Another possibility to enhance mass transfer is provided by *rotating electrodes.* As an example, the rotating cylinder electrode cell [108] is shown schematically in Figure 25. In this case the steep velocity gradient near the electrode surface, which induces a high mass-transfer rate, is not obtained by rapid motion of the fluid, but by rotation of the electrode. The mass-transfer equation of the rotating cylinder electrode is [109]

$$Sh = 0.079 Sc^{0.356} Re^{0.7}$$

$$Sh = \frac{k_m r}{D}, \; Sc = \frac{\nu}{D}, \; Re = \frac{r^2 \omega}{\nu}$$

Figure 24. Parallel-plate cell with turbulence promoters

Figure 25. Cell with rotating cylinder electrode

The mass-transfer coefficient increases with the 0.7th power of the rotation velocity and the 0.4th power of the cylinder radius. Rotating cylinder electrode cells are used to recover silver from photographic effluents (see Chap. 4.6).

The *trickle tower cell* [110, 111, 112], depicted in Figure 26, is easy to construct and scale up. It is composed of several layers of conducting disks or particles separated from each other by insulating mesh. Each particle layer acts as a bipolar electrode. If the space between the particles is large enough, the trickle tower can also be used to produce gases, since the electrolyte flows as a film around the particles, and the gas may be removed via the electrolyte-free space in the tower. Rinsing a thin electrolyte film around the particles ensures bipolar operation, even for highly conducting electrolytes, because of the large electrolyte resistance parallel to the electric field. However, the trickle tower cell is restricted to cell reactions that can be carried out in an undivided cell, and is especially useful for cases involving a three-phase (gas – liquid – solid electrode) reaction.

A cell design combining ease of construction and scale up with a small interelectrode gap is the *capillary gap cell* [113], which is shown in Figure 27. It consists of a stack of bipolar circular electrode disks separated by nonconducting spacers. The electrolyte enters via a central channel and is radially distributed between the electrodes.

Although this design is an undivided cell, it can also be used to avoid reconversion of the products at the counterelectrodes. This can be achieved by a careful tuning of disk geometry and flow velocity to ensure that the diffusion layer thicknesses, which increase along the radius, do not reach the counterelectrodes [114]. By this means the products formed at the electrodes are prevented from contacting the counterelectrode. However, the products must be removed, e.g., by extraction, before the electrolyte can be recycled. Whereas the scale up of the stack height and the number of electrode disks is simple, the outer disk radius cannot be enlarged without limit. The slower linear flow velocity along the radius lowers the local mass-transfer coefficient [115], which lowers the mean current density and therefore the space – time yield as the outer radius is scaled up. The decreasing mass-transfer coefficient along the radial flow direction is avoided by the *pump cell* [116], [117], which is shown in Figure 28. A disk rotating around a central shaft is placed between two stationary electrode disks. By this means a tangential velocity component, which is caused by disk rotation and which increases along the

Figure 26. Trickle tower cell

Figure 27. Capillary gap cell

radius, is superimposed on the radial flow velocity component, which decreases along the radius. This modified flow pattern keeps variation of the local mass-transfer coefficient and current density with the radius small [118]. The number of electrodes can be easily increased by always placing one stationary electrode between two rotating electrodes. Operation is bipolar, alleviating the need to contact rotating electrodes. The rotation pumps the liquid through the gaps of the stack.

An effective, surprisingly simple cell design for undivided cells is offered by the *Swiss-roll cell* [119], [120]. Two metal foils acting as electrodes are separted from each other by two insulating plastic meshes or tissues that act as turbulence promoters and are rolled up (Fig. 29). This cell simultaneously provides large specific electrode area and low ohmic voltage drop. Because of the thinness of the electrodes and their resistance a nonuniform current distribution results if the electrode contacts are positioned at the same end. However, this can be avoided by contacting the electrodes at opposite ends: one electrode contact is in the center of the roll, and the other is at the periphery. Scaling up of the electrode lengths then does not cause any trouble, but this is at the expense of a higher total cell voltage [121].

Figure 28. Pump cell

A cell design strictly directed toward minimization of the ohmic voltage drop in the electrolyte, especially if gases are evolved at the electrode, is the *zero-gap cell* [122], [123]. As

Figure 29. Swiss-roll cell

Figure 30. Electrode arrangement of a zero-gap cell

Figure 31. Gas evolution and current distribution at perforated-plate zero-gap electrodes

Figure 32. Solid polymer electrolyte (SPE) cell

shown in Figure 30, electrode meshes or perforated electrodes are pressed directly onto the diaphragm or the membrane by suitable current collectors, which simultaneously provide optimum electrode contact across the whole electrode area. This expedient avoids larger current crossways, which would give rise to an additional ohmic voltage drop. However, in such zero-gap cells, especially if equipped with perforated electrodes, an uneven current distribution arises, which is illustrated by Figure 31: the diaphragm cross section available for current flow is decreased to the vacant area of the electrodes, which increases the ohmic voltage drop across the diaphragm. The current must pass through the less conductive gas-containing electrolyte. A nonuniform current distribution is established around the electrode holes, requiring optimization of hole diameter and spacing, which depends on the current density. Zero-gap cells have been successfully used for alkaline water electrolysis [122], [123].

Ion-exchange membranes can be modified by putting the electrocatalyst directly onto the membrane surface [124]. Because of the surface resistance of the catalyst layers, the catalyst must be contacted by conducting, porous current collectors allowing the transport of dissolved reactants and gaseous products (Fig. 32). Such a cell – called the *solid polymer electrolyte* (SPE) *cell* – is used for water electrolysis (see page 48) and chlor-alkali electrolysis and has also been investigated for organic electrosyntheses (see page 102).

3.6. Cells with Three-Dimensional Electrodes

The rate of conversion in electrochemical cells is proportional to the electrode surface area. This is the incentive for designing electrochemical cells with a high electrode surface-to-volume ratio as actualized in porous electrodes, packed-bed electrodes, or fluidized-bed electrodes, which are usually referred to as three-dimensional electrodes [125, 126, 127, 128, 129, 130]. In these three-dimensional cells, not only the mass-transfer problem but also the current-distribution problem must be solved.

The current and potential distribution is mainly affected by the cell geometry, especially by the relative arrangement of the three-dimensional electrode and the counterelectrode. In regard to the relative directions of current and electrolyte flow there are two electrode arrangements: flow-through (current and electrolyte flow parallel) and flow-by (current and electrolyte flow perpendicular). For industrial applications, flow-by electrodes are preferred since they provide a longer residence time and therefore a greater degree of conversion per cycle. These two possibilities are illustrated in Figure 33.

In Figure 33, configuration A acts approximately as a differential reactor and has been mainly used for fundamental kinetic studies [131]. Arrangement B has been investigated as a rotating packed-bed electrolyzer [130] and as a radial flow-through electrode [132]. The cubic flow-by design (Fig. 33D) has been applied for fluidized-bed electrodes [126], [132, 133, 134, 135]. For packed-bed electrodes, the same design may be used with the modification of a variable depth (parallel to current flow) along the direction of electrolyte flow [136, 137, 138, 139]. Configuration F is the elementary unit of a design successfully applied in industry for the removal of copper from dilute acidic electrolytes [140, 141, 142].

The kinetic characteristics of a three-dimensional electrode are illustrated in Figure 34, which compares polarization curves for silver deposition from 10^{-3} m Ag^+ at identical flow velocities u for planar electrodes in a channel and for a flow-through packed-bed electrode. The curves for the planar electrodes indicate diffusion-controlled silver deposition. For the bed electrode, the diffusion-limited current density is ca. 100 times greater than that for the planar electrode, due to the larger actual electrode surface as well as to the enhanced local mass-transfer rate within the packed-bed electrode.

The mass-transfer coefficient can be obtained from

$$Sh = C\,Sc^{1/3}\,Re^{m}$$

In this case

$$Sh = \frac{k_{\mathrm{m}}\,v\,d_{\mathrm{p}}}{(1-v)\,D},\quad Sc = \frac{\nu}{D},\quad Re = \frac{u\,d_{\mathrm{p}}}{(1-v)\,\nu}$$

where v is the bed voidage and d_{p} the particle diameter

Figure 34. Polarization curves for silver deposition [33]
A) Plane electrode in a channel; B) Flow-through 4.6-mm packed-bed electrode

Some values for C and m are listed in Table 4. The variation in these constants from different references emphasizes the uncertainty in the values of mass-transfer coefficients. For spherical particles the specific electrode area is given by

$$a_{\mathrm{e}} = \frac{6\,(1-v)}{d_{\mathrm{p}}}$$

Table 4. Constants for mass-transfer correlations

System	C	m	Re	Ref.
Packed bed	0.50	0.61	50 – 5000	[143]
	0.32	0.66	100 – 10 000	[144]
Fluidized bed	5.7	0.22	1 – 30	[145]
	1.52	0.5	2 – 7	[146]
	0.29	0.75	100 – 5000	[144]

The macrokinetic behavior of three-dimensional electrodes expressed by the packed-bed polarization curves in Figure 34B can be explained by the potential distributions shown in Figure 35.

The *bed current density* plotted in Fig. 34 is defined as

$$j_{\mathrm{b}} \equiv a_{\mathrm{e}} \int_0^h j\,[\eta\,(x)]\,\mathrm{d}x$$

where h is the bed height and $j\,[\eta\,(x)]$ in general is represented by the expression

$$j\,[\eta\,(x)] = \frac{j_0\,[\exp\,(\alpha_{\mathrm{a}}\eta\,(x)) - \exp\,(-\alpha_{\mathrm{c}}\eta\,(x))]}{1 + \frac{j_0}{j_{\mathrm{l}}^{\mathrm{a}}}\exp\,(\alpha_{\mathrm{a}}\eta\,(x)) - \frac{j_0}{j_{\mathrm{l}}^{\mathrm{c}}}\exp\,(-\alpha_{\mathrm{c}}\eta\,(x))}$$

with

$$\alpha_{\mathrm{a}} = \frac{\beta^{+}F}{RT}\,,\ \alpha_{\mathrm{c}} = \frac{\beta^{-}F}{RT}\,,$$
$$j_0 = j_0' \prod_i c_i^{\nu_i}\,,\ j_{\mathrm{l}}^{\mathrm{a,c}} = k_{\mathrm{m}} z F c$$

For a mass-transfer-controlled reaction, the general expression simplifies to

$$j\,[\eta\,(x)] = j_{\mathrm{l}}\left[1 - \exp\left(-\frac{zF}{RT}\eta\,(x)\right)\right]$$

and for an activation-controlled reaction the Butler – Volmer equation (Eq. 2) can be applied. The local overvoltage is

$$\eta\,(x) = \phi_{\mathrm{p}}\,(x) - \phi_{\mathrm{s}}\,(x) - \Delta\phi_{\mathrm{eq}} \text{ with } \eta\,(0) = \eta_{\mathrm{B-F}}$$

Figure 35. Schematic potential distributions
A) Packed-bed electrodes and B) Fluidized-bed electrodes [33]

For a packed-bed electrode, $\eta\,(x)$ decreases along the bed height x as can be seen in Figure 35A. For diffusion-controlled silver deposition, 99 % of the limiting current density is reached at an overvoltage of 0.120 V; i.e., the bed electrode reaches its limiting current density at a depth h where

$$\eta\,(h) = \phi_{\mathrm{p}}\,(h) - \phi_{\mathrm{s}}\,(h) \geq 0.120\,\mathrm{V} \tag{21}$$

However, $\eta_{\mathrm{B-F}}$, which serves as the reference for the potential axis in Figure 35, is already larger than 0.120 V, which explains that with a

Figure 36. Partial and overall (— theoretical, ····· experimental) polarization curves for the electrolyte 10 ppm Cu^{2+}, 5 ppm Fe^{3+}, and 3 ppm O_2 at pH 3.5
The electrode potential is versus the NHE.

bed electrode the limiting current density is approached at higher potentials than with a plane electrode. If the flow rate is increased, the mass transfer coefficient increases, which results in a larger diffusion-limited current density j_l. For a given local overvoltage, a larger j_l yields a higher microkinetic current density $j\,[\eta\,(x)]$. Because of Ohm's law the $\phi_s\,(x)$ curve in Fig. 35 becomes steeper, and the η_{B-F} value that corresponds to Equation 21 becomes still larger.

The calculation of the macrokinetic bed current density requires quantitative knowledge of the potential functions $\phi_p\,(x)$ and $\phi_s\,(x)$.

According to Ohm's law, for three-dimensional electrodes of cubic geometry (Fig. 33A and D) the following pair of second-order differential equations are valid [4], [125], [131], [139], [147], [148]:

$$\frac{d^2\phi_s}{dx^2} = -a_e \frac{j\,[\eta\,(x)]}{\kappa_s}$$

$$\frac{d^2\phi_p}{dx^2} = a_e \frac{j\,[\eta\,(x)]}{\kappa_p}$$

For electrodes of concentric geometry the corresponding differential equations are

$$\frac{d^2\phi_s}{dr^2} + \frac{1}{r}\frac{d\phi_s}{dr} = -a_e \frac{j\,[\eta\,(x)]}{\kappa_s}$$

$$\frac{d^2\phi_p}{dr^2} + \frac{1}{r}\frac{d\phi_p}{dr} = a_e \frac{j\,[\eta\,(x)]}{\kappa_p}$$

To solve these systems of differential equations two boundary conditions are necessary for each equation. The boundary conditions for cell geometries A – F depicted in Fig. 33 are as follows:

A and D:

$$\phi_s\,(0) = 0 \qquad \phi_s\,(h) = \eta_{B-F} \qquad \frac{d\phi_p(0)}{dx} = \frac{d\phi_s(h)}{dx} = 0$$

B and E:

$$\phi_p\,(r_1) = \eta_{B-F} \qquad \phi_s\,(r_2) = 0 \qquad \frac{d\phi_s(r_1)}{dr} = \frac{d\phi_p(r_2)}{dr} = 0$$

C and F:

$$\phi_s\,(r_1) = 0 \qquad \phi_p\,(r_2) = \eta_{B-F} \qquad \frac{d\phi_p(r_1)}{dr} = \frac{d\phi_s(r_2)}{dr} = 0$$

In the general case the differential systems of equations can only be solved numerically. For limiting current electrodes – at each point of the electrode the microkinetic limiting current density is established – the substitution

$$j\,[\eta\,(x)] = k_m z F c = j_l$$

permits an analytical solution for the cubic geometry.

For cubic electrodes, the bed depth corresponding to a given potential variation $\Delta\eta$ can be expressed [131] for a fluidized-bed electrode

$$\kappa_p \geq \kappa_s \quad h = \left[\frac{2\Delta\eta}{a_e j_l \left(\frac{1}{\kappa_s} - \frac{1}{\kappa_s + \kappa_p} \right)} \right]^{0.5}$$

$$\kappa_p \leq \kappa_s \quad h = \left[\frac{2\Delta\eta}{a_e j_l \left(\frac{1}{\kappa_p} - \frac{1}{\kappa_s + \kappa_p} \right)} \right]^{0.5}$$

and for a packed bed electrode

$$\kappa_p \gg \kappa_s \quad h = \left[\frac{2\kappa_s \Delta\eta}{a_e j_l} \right]^{0.5} \tag{22}$$

For flow-through electrodes acting as differential reactors, the concentration of the reacting species may be considered as constant within the electrode. Modeling of flow-by electrodes requires an additional consideration of the concentration change along the electrolyte flow direction, which is given by the ideal tube-reactor equation:

$$\frac{dc}{dy} = -a_e \frac{k_m c}{u}$$

In fluidized-bed electrodes, the effective particle conductivity κ_p is determined by collision statistics since charge can be transferred through the particle phase only during particle collisions. Several theories for this have been discussed in the literature [149], [150] but the following formula shows reasonable accuracy [151]:

$$\varrho_p = \frac{u_p C}{0.159 \varepsilon^{1/3} \left(\varepsilon^{1/3} - 1 \right)}$$

where u_p represents the mean particle velocity, C is the double-layer capacity, and ε represents the height of the fluidized bed divided by that of the packed bed.

As an example for the complexity of fluidized-bed electrode behavior, the deposition of copper from an electrolyte containing 10 ppm Cu^{2+}, 5 ppm Fe^{3+} and 3 ppm O_2 at pH 3.5 may be considered [152]. The partial and the overall polarization curves are shown in Figure 36.

For a cubic flow-by fluidized-bed electrode (Fig. 33D) and the same electrolyte, the potential distributions along the flow length y ($y = 0$ corresponds to the electrolyte inlet) and the current-flow direction x (bed depth, $x = 0$ corresponds to

Figure 37. Electrolysis in a cubic flow-by fluidized-bed electrode
A) Potentials; B) Total current density; and C) Copper concentrationThe electrolyte contains 10 ppm Cu^{2+}, 5 ppm Fe^{3+}, and 3 ppm O_2 at pH 3.5.

the diaphragm plane) are shown in Figure 37A. The low overpotentials at the center of the inlet are responsible for low local current densities in this region (see Fig. 37B). The increasing current density tails at the electrode outlet are due to the beginning hydrogen evolution in these regions. The current density minimum at the inlet causes delayed copper depletion in the middle of the electrode as can be seen in Figure 37C.

Three-dimensional electrodes have industrial applications [153]. Packed-bed electrodes are mainly used for removal of metals from wastewaters (see Chapter 4.6). Fluidized-bed electrodes are more suitable for metal winning from solutions containing ca. 0.5 – 10 g of metal per liter, i.e., dilute solutions, since they allow the deposition of larger amounts of metal than packed-bed electrodes and the degree of conversion per pass of electrolyte is usually in the range of 90 %. Such applications have been described [130], [132, 133, 134, 135], [152], [154, 155, 156, 157, 158, 159]. This process has been used industrially by AKZO [141], [142].

Insight into the economic situation of metal winning by fluidized-bed electrolysis is given by Figure 38. For a specific investment cost of an available fluidized bed electrolysis plant of $0.142\,\mathrm{DM\,h^{-1}\,L^{-1}}$ ($1.8\,\mathrm{DM} \approx \$\,1$) the economic concentration limit is plotted as a function of the normalized space velocity ϱ_s^n [104], [160] and the metal price [152].

Figure 38. Economic lower limits of metal-ion concentration as a function of metal price and normalized space velocity ϱ_s^n for fluidized-bed electrolysis

3.7. Electrochemical Nanostructuring with a Scanning Tunneling Microscope

With the invention of the scanning tunneling microscope (STM) in the early 1980s by G. Bining and H. Rohrer [161], [162] a structure-sensitive technique for studies of the electrode – electrolyte interface with atomic-scale resolution has become available for electrochemists.

Besides imaging surface structures, the STM can also be used to manipulate surfaces on a nanometer scale [163], [164]. This so-called nanostructuring, the miniaturization of surface structures, is becoming increasingly important in areas such as electronic devices, sensors, and the tayloring of catalysts. Electrochemists have started to put into practice an electrochemical nanotechnology using the STM for nanostructuring electrode surfaces. This can be achieved, e.g., by creating tip-induced surface defects which then act as nucleation centers for metal deposition at preselected positions [165], [166].

In 1997 a novel process has been explored for making metal nanoclusters with the help of an STM [167, 168, 169]. The suggested mechanism for this tip-induced cluster generation is sketched in Figure 39. By applying a tip potential which is more negative than the bulk deposition potential for the metal ions in solution, metal is deposited from the electrolyte onto the tip (Fig. 39 B). The metal-loaded tip is then made to approach the surface for a short time so that a so-called jump-to-contact [170] can occur and a metal bridge between tip and surface is formed (Fig. 39 C). During the retreat of the tip the connective neck breaks and leaves a small cluster on the substrate (Fig. 39 D).

Figure 40 shows 12 Cu clusters, which were arranged in a circle on a Au(111) surface (the Au surface is covered with a monolayer of Cu at $E_{\mathrm{sample}} = 10\,\mathrm{mV}$ vs. $\mathrm{Cu/Cu^{2+}}$ due to underpotential deposition). Each of the clusters is about 0.8 nm in height (4 monolayers of Cu), the full width at half maximum (FWHM) of the clusters as imaged with the STM is about 3.5 nm, which yields an estimated 100 Cu atoms per cluster.

The electrochemical stability of these clusters is remarkable: at an electrode potential of $+10\,\mathrm{mV}$ vs. $\mathrm{Cu/Cu^{2+}}$ they remain practically unchanged for at least 1 h [168], [171]. By use of a microprocessor-controlled tip movement a large amount of clusters can be generated au-

Figure 39. Suggested mechanism for the tip-induced metal deposition

Figure 40. STM image of 12 Cu clusters on a Au(111) electrode in 0.05 M H_2SO_4 + 1 mM $CuSO_4$
E_{sample} = + 10 mV vs. Cu/Cu^{2+}; E_{tip} = − 50 mV vs. Cu/Cu^{2+}; I_{tunnel} = 2 nA [169]

tomatically, e.g., an array of 10 000 Cu clusters was generated with a rate of 50 Hz [172]. One advantage of this method is that no depletion of the deposited metal occurs, even when a large amount of clusters is produced, because the tip potential guarantees a continuous refill of metal on the tip.

It is not only possible to position the Cu clusters exactly, but also their size can be varied within certain limits [169], [171]. This is done by varying the approach of the tip: the closer the tip approaches the surface the more material is transferred (up to the point where tip and sample get into mechanical contact); if the tip approach is not close enough, no material is transferred, because a jump-to-contact cannot occur.

This method is not restricted to the system Cu/Au(111). Figure 41 shows an array of 400 Pd clusters on Au(111), the height of the clusters ranging between 0.2 and 0.6 nm. The generation of nanometer-sized particles of catalytically active metals such as Pd may be important for studying relations between catalytic activity

Figure 41. STM image of 400 tip-generated Pd clusters on Au(111) in 0.05 M H_2SO_4 + 1 mM H_2PdCl_4 E_{sample} = + 0.66 V; E_{tip} = + 0.48 V vs. SCE; I_{tunnel} = 2 nA [173]

and size of the clusters. Other systems are discussed in [171].

Present research centers on the nanostructuring of semiconductor surfaces with small metal clusters [174], because of the tremendous importance of small metal-semiconductor junctions for use in electronic devices, and the possibility of generating artificial structures from magnetic metals like Ni or Co is investigated.

4. Inorganic Electrochemical Processes

A number of inorganic substances are produced by electrochemical processes. Typical examples are the chlor-alkali process, which produces chlorine and caustic soda or chlorine oxides, chlorine oxygen acids, and their salts and hydrogen, the electrolysis of water to produce hydrogen and oxygen, and the anodic oxidation of aqueous sulfuric acid solutions to produce peroxodisulfuric acid and its salts. Electrochemical processing of metals is used to produce (electrowinning) and purify (electrorefining) copper, nickel, zinc, lead, aluminum, sodium, and magnesium, among others. Nuclear fuels and wastes can be processed electrochemically, and wastewaters can be purified by electrodeposition of heavy metals.

Anodic dissolution is the basis of electrochemical shaping, in which a cathodic tool is used to give a metal a particular shape (electrochemical machining or grinding) or a smooth surface (electropolishing).

4.1. Chlor-Alkali Electrolysis

The products of industrial chlor-alkali electrolysis are of great importance for the chemical industry: chlorine [*7782-50-5*], caustic soda [*1310-73-2*], hypochlorite, chlorate, and perchlorate. The rate of chlorine production is considered one of the measures of the industrial standing of a nation. Of the electrochemical processes, chlor-alkali electrolysis holds second place in total electrical energy consumption, aluminum production consuming more.

In industrial chlor-alkali electrolysis, the electrolyte is generally aqueous sodium chloride solution, to a much lesser extent potassium chloride solution. For the production of sodium

metal, fused sodium chloride is used. In all cases, the primary anodic reaction is the oxidation of the chloride ion, in itself a relatively simple reaction,

$$Cl^- \longrightarrow \tfrac{1}{2}\,Cl_2 + e^-$$

but this reaction can be accompanied or followed by other reactions. At the cathode, various reactions can take place: the products depend on the operating conditions. Chlor-alkali electrolysis justifies a detailed survey, not only on account of its economic importance, but also because of the interesting reaction technology. It is an excellent example of the way in which one anode reaction, from one raw material, can lead to a great variety of products, according to the way in which secondary reactions are prevented, encouraged, or controlled by the design of the equipment and choice of the reaction conditions. The introduction of dimensionally stable anodes based on ruthenium oxide – titanium oxide [175], which replaced the conventional graphite anodes in all aqueous chloride electrolyses, has contributed to far-reaching process modifications within the last three decades.

4.1.1. Molten Salt Electrolysis

In molten salt electrolysis, the cathodic reaction

$$Na^+ + e^- \longrightarrow Na$$

yields sodium [*7440-23-5*], which is of lower density than the melt, floats to the surface, and is then easily separated. Futher reaction of the two products does not take place, provided recombination is prevented. The high cell voltage makes the process useful only for winning sodium (→ Sodium und Sodium Alloys). Chlorine is in this sense a byproduct.

4.1.2. Production of Chlorine

Processes designed to produce chlorine are always based on electrolysis of aqueous chloride solutions, below 100 °C. The decomposition voltage is much lower than that for molten salt electrolytes. This technology is, however, considerably complicated by the secondary reactions of the primary electrolysis products and by side reactions.

The dissolved chlorine formed at the anode reacts with water to form hypochlorite,

$$Cl_2 + H_2O \longrightarrow HClO + Cl^- + H^+$$

The electrolyte near the anode becomes acidic. If the electrolyte is not replaced, or not replaced quickly enough, the supersaturation of chlorine at the anode increases to such an extent that stable chlorine bubbles form. Acidic electrolyte is the precondition of chlorine gas formation in aqueous solution. If the anode boundary layer is neutralized, the formation of gaseous chlorine is prevented. This situation arises if no steps are taken to prevent mixing of anolyte and catholyte.

At the cathode, hydrogen gas and hydroxyl ions are liberated simultaneously from aqueous solution:

$$2\,H_2O + 2e^- \longrightarrow H_2 + 2\,OH^-$$

There are two ways of ensuring the formation of gaseous chlorine: one is to prevent the hydroxyl ions from reaching the anode region, the other is to prevent the formation of these ions at the cathode in the first place. Both approaches are used in industry and have led to two technologies. One of these, the mercury process, uses mercury as the cathode material. The other technology uses cells divided by either a diaphragm or a membrane.

Mercury Process. Mercury [*7439-97-6*], the liquid cathode, is able to alloy the liberated sodium forming sodium amalgam (Fig. 42).

$$Na^+ + nHg + e^- \longrightarrow NaHg_n$$

The evolution of hydrogen is prevented by the exceptionally high overpotential of hydrogen at mercury surfaces. Hydroxyl ions are not formed. The amalgam increases in viscosity rapidly, so the sodium concentration must be kept low (< 0.3 wt % Na). High-load mercury cells require increased mercury throughputs. Outside the electrolysis cell, the amalgam is treated in a decomposer, a short-circuited galvanic cell. Here the sodium is liberated, and sodium hydroxide solution and hydrogen are formed. The caustic soda solution is both extremely pure and highly concentrated (50 wt %), but the high cell voltage, more than 1 V higher than that required

Figure 42. Mercury Process
a) Cell; b) Decomposer

for the competitive processes, and the toxicity of mercury have discouraged use of the highly developed mercury process.

Diaphragm Process. The diaphragm process allows the formation of hydroxyl ions but prevents their movement towards the anode region. The process uses cells divided into compartments by diaphragms made of microporous materials such as asbestos or synthetic polymers. These materials permit the flow of electrolyte but do not allow the OH^- ions to leave the cathode region if there is a sufficient flow of electrolyte from the anode into the cathode chamber, i.e., if the linear velocity of the electrolyte within the diaphragm is somewhat greater than the migration velocity of the OH^- ions in the electric field (Fig. 43A). This method allows high current efficiencies, but the sodium hydroxide that is formed is contaminated with chloride. Further treatment, such as evaporation and crystallization to remove sodium chloride, is unavoidable and expensive, which reduces the economy of the process [176]. And, unless special purification procedures are used, the alkali product (50 wt % NaOH) is contaminated with 1.3 wt % NaCl. The low cell voltage is an advantage, but the electrical resistance of the diaphragm produces an additional potential difference.

Membrane Process. The development of efficient cation-exchange membranes has in general made the diaphragm process obsolete. Fluorinated cation exchange membranes are used. Unlike diaphragms, membranes prevent the hydrodynamic flow of water but permit cation transfer by cation migration, and they enable the almost complete separation of anolyte and catholyte (Fig. 43B). However, the highly mobile hydroxyl ions cannot be completely prevented from crossing the membrane. High alkali concentration in the cathode region favors OH^- diffusion, contributes to buffering of the anolyte, and promotes hypochlorite formation and its anodic oxidation. The extent of these effects may be gauged by monitoring the oxygen content of the chlorine. As a result, efforts are being made to counteract hydroxide migration by improvements in plant operation, plant design, and membrane quality.

The membrane is not completely impermeable to water: the hydrated alkali-metal ion transports a part of its water through the membrane and water arrives at the catholyte side, preventing the concentration of the alkali from attaining the values reached in the mercury process.

Oxygen-Reducing Cathodes. Instead of a hydrogen-evolving electrode, an oxygen-reducing cathode can be used. This alternative allows substantial reduction (ca. 1 V) in cell voltage. Due to its purity, the catholyte of membrane cells is particularly appropriate for the use of air instead of pure oxygen. The high cost of

the membranes calls for high current density, ca. 3000 A/m^2, which today cannot yet be met by oxygen-reducing cathodes. The potential cell voltage reduction should stimulate further development [177].

Figure 43. Diaphragm and Membrane Processes
A) Diaphragm cell; B) Membrane cell

For a detailed description of chlorine production → Chlorine.

4.1.3. Electrosynthesis of Hypochlorite

In undivided cells hypochlorite is formed instead of chlorine.

$$2Cl^- \longrightarrow Cl_2 + 2e^-$$
$$Cl_2 + H_2O \longrightarrow HClO + Cl^- + H^+$$

Hypochlorite is, however, not stable. In addition, it can be converted by anodic oxidation to chlorate or cathodic reduction to chloride. Both reaction rates are mass-transfer controlled. Therefore, high hypochlorite concentrations are impossible to obtain under the conditions for anodic chloride oxidation. The upper concentration limit is ca. 10 g/L. High production rates are possible only if the chloride solution is passed through the cell at high velocity, which also favors mixing of the electrolyte and prevents formation of chlorine gas. But, unfortunately, high electrolyte velocity favors mass transfer of hypochlorite already formed, thus lowering the current efficiency. An understanding of these relationships is necessary to optimize the production of hypochlorite by correct design and operation of the plant.

4.1.4. Electrosynthesis of Chlorate

Higher world tonnages are produced by this process than by any other inorganic electrosynthesis. There is no separator between the electrodes in the reactors, and mixing of the electrolyte is an integral feature of the process. The electrolyte, a concentrated sodium chloride solution similar to that used in chlorine production, flows at a high rate through the region between the electrodes. The formation of chlorate, rather than hypochlorite, is encouraged by design and operation of the installation. Chlorate is formed from hypochlorite by two mechanisms, by anodic oxidation

$$3\,ClO^- + 1.5\,H_2O \longrightarrow ClO_3^- + 3\,H^+ + 2\,Cl^- + 0.75\,O_2 + 3\,e^-$$

and by partial disproportionation of hypochlorous acid and subsequent autoxidation

$$2\,HClO + ClO^- \longrightarrow ClO_3^- + 2\,Cl^- + 2\,H^+$$

This chemical formation of chlorate is the desired reaction in industrial production because, in contrast to anodic oxidation, additional electrical energy is not required.

The anodic oxidation of hypochlorite is mass-transfer limited, and the rate is therefore proportional to the electrode surface and the residence time of electrolyte in the interelectrode

gap. The chemical formation, however, is homogeneous, and today all chlorate plants are provided with a comparatively large holding volume in addition to the space between the electrodes, this volume being either integral with the electrolyzer or constructed as a separate unit through which the electrolyte passes. The velocity between the electrodes is high, of the order of 1 m/s. Although this favors the mass transfer of the hypochlorite to the anode, it reduces the residence time in the interelectrode gap. Further conditions favorable to the chemical formation of hypochloric acid are temperatures of 80 – 90 °C, as attainable in modern cells with dimensionally stable anodes, and an optimum pH of 6.1 – 6.4.

4.1.5. Electrosynthesis of Perchlorate

In perchlorate electrosynthesis, the cell is undivided. Perchlorate is formed solely by anodic oxidation of chlorate. There is, however, a competing reaction, namely the anodic oxidation of water, and this has almost the same standard electrode potential. The relative rate of these two reactions is not significantly affected by pH or other operating conditions. However, the anode potential, which should be high, is of great importance. The process may be optimized only by suitable choice of the material of construction and physical state of the anode. Not surprising then, in contrast to the other process discussed, there has been no significant recent improvement in perchlorate manufacturing technology.

For a detailed description of hypochlorite, chlorate, and perchlorate production → Chlorine Oxides and Chlorine Oxygen Acids.

4.2. Water Electrolysis for Hydrogen Production

Electrolytic splitting of water [*7732-18-5*] ($\Delta G^0 = 241.9$ kJ/mol, $\Delta H^0 = 286.66$ kJ/mol) corresponds to a decomposition voltage of only 1.2 V and electrical energy consumption per 1 m^3 of H_2 (STP) of only 2.95 kWh, whereas the combustion enthalpy per 1 m^3 of H_2 (STP) of 3.68 kWh corresponds to a "thermoneutral cell voltage" of ca. 1.5 V. In this section, production in m^3 always refers to 1 m^3 of H_2 (STP). The present technology, with cell voltages of ≥ 1.9 V and energy consumption of 4.7 – 4.8 kWh/m^3, is still far greater. Water electrolysis is a long-established technique for producing hydrogen [*1333-74-0*] on a commercial scale. Nevertheless, it has gained only limited acceptance for large-scale production. In general, electrical energy, the cost of which constitutes more than half the cost of hydrogen production by water electrolysis, is too expensive to make electrolytic hydrogen competitive with hydrogen obtained by steam reforming of natural gas or oil.

Table 5 presents some information on the few large-scale water electrolysis plants; however, the facilities in Norway are closed now because even there hydroelectricity became too expensive. Nonetheless, the socalled energy crisis of 1972, together with potentially more extensive use of nuclear and renewable energies, has led to remarkable efforts to improve the established techniques – in particular alkaline water electrolysis – and to develop new ones – in particular membrane or solid polymer electrolyte (SPE) and high-temperature steam electrolysis.

Alkaline Water Electrolysis. With the exception of the Noranda electrolyzer, all electrolyzers of substantial power (> 0.1 MW) currently on the market (Tables 6 and 7) are bipolar electrolyzers with forced convection of the electrolyte. All, with the exception of the newly developed Hydrogen Systems (H. S.) and the MTU electrolyzers, use asbestos diaphragms as separators, and most electrolyzers on the market approach zero-gap geometry.

All electrolyzers are operated with 25 – 35 wt % KOH (with the exception of the H. S. electrolyzer, which uses 14 wt % NaOH), and

the process temperature is generally above 75 °C, with an upper limit of 90 °C for the Lurgi and of 130 °C for the MTU electrolyzer.

Most of the electrolyzers work under ambient pressure, leaving compression of the product gases, if necessary, to compressors. Only the Lurgi and MTU electrolyzers, which in some ways represent the most ambitious technique, work under medium pressure, 3 MPa, whereas the newly developed H. S. electrolyzer operates at an only moderately enhanced pressure of 0.7 MPa. Low-temperature operation (< 80 °C) under ambient pressure permits the use of light equipment such as normal steel for electrodes, cells, pipes, pumps, etc., and helps keep investment costs low. Higher temperature and pressure call for heavier construction and for more care in particular to selection of steels with reliable corrosion stability and insensitivity towards stress corrosion cracking.

The advantages of higher temperatures and pressures are, however, convincing with respect to power consumption. Higher temperatures reduce the cell resistance because of improved electrolyte conductivity and reduce the electrode overpotentials due to thermal activation of the electrode process. High pressure reduces the volume of the evolved gases and gas holdup in the cell and thus reduces the effective electric resistance of electrolyte.

Figure 13 depicts a cell voltage – current density curve that is typical for the present electrolyzer generation having effective surface specific resistance around $1\,\Omega\,cm^2$. For improved pressurized electrolyzers this resistance is some 70 to 80 % less (Fig. 44). The steep increase of cell voltage with current density – mainly due to the relatively high cell resistance – is a good reason to keep current densities in conventional electrolyzers low, 0.2 – 0.3 A/cm^2, thus conserving expensive electrical energy. Only the

Lurgi electrolyzer in its most modern version, the MTU and the H. S. electrolyzers aim at current densities upwards of 0.5 A/cm^2 and can do so because of their relatively low surface specific resistances.

Figure 44. Current – voltage curves for advanced alkaline water electrolysis [178]

The three most advanced electrolyzer technologies allow hydrogen production with an energy consumption of 3.8 kWh/m^3 at current densities as high as 0.8 A/cm^2. This energy consumption approaches the water-splitting enthalpy of 3.68 kWh/m^3.

Electrocatalysis. Relatively little effort is needed to catalyze the cathode reaction. Most commonly used are high surface area nickel layers, either Raney nickel [*7440-02-0*] or porous nickel coatings produced in situ by cathodic reduction of nickel sulfide coatings.

$$Ni_2S_3 + 6\,e^- \longrightarrow 2\,Ni + 3\,S^{2-}$$

Leachable Ni_2S_3 coatings are obtained either by cathodic nickel deposition from galvanic Ni^{2+} baths containing sulfur donors (thiosulfate, thiourea, thiocyanate, and similar compounds) or by sulfidizing nickel electrodes in an atmosphere containing hydrogen sulfide. Raney nickel coatings can be applied on steel or nickel electrodes by cold-rolling [179]: the Raney nickel (Ni – Al prealloy containing 50 wt % Ni, corresponding approximately to stoichiometry $NiAl_3$) is bonded by pressure and shear to the electrode and is stabilized by subsequent annealing on the electrode. A second method consists of cathodically depositing Ni – Zn alloys containing Ni : Zn ratios in the range 1 : 1 to 2 : 1 [180]. Such coatings are relatively thin, between 50 and 150 µm. The well-established theory of porous electrodes indicates that the penetration depth of the current in these highly porous electrocatalysts is ca. 100 µm for current densities around 1 A/cm^2.

Improvements for advanced electrolyzers aim at decreasing cell resistances, the objective being to increase current densities above 0.5 A/cm^2 and still decrease cell voltages below the values used in the established technology. Electrocatalysis, especially at the anode, is now being introduced for the established electrolyzers as well.

Prior to public disclosure of the results of the recent research and development almost the only anodic electrocatalyst was nickel or nickel-coated steel anodes. NiO, or rather NiOOH, is by itself – compared to other metal oxides – a relatively effective electrocatalyst to enhance anodic oxygen evolution, and allows the use of an anodic overpotential lower than + 280 mV at current densities of 0.1 – 0.2 A/cm^2 at 90 °C in 30 wt % KOH.

Coatings of mixed oxides containing cobalt oxide such as cobalt nickel calcium perovskite and lanthanum nickelate ($Ca_{0.2}Co_{0.8}LaO_3$–$NiLaO_3$), cobalt nickel spinel (Ni_2CoO_4), and cobalt spinel (Co_3O_4), and iron – cobalt mixed spinel have proved to be relatively efficient electrocatalysts for anodic oxygen evolution. Indeed, the new H. S. electrolyzer is known to use Co_3O_4 coatings at the anode.

Diaphragms. Most impressive are the advances made in replacing the thick asbestos diaphragm – its thickness causing excessive electrolyzer resistances – by much thinner, mechanically strong diaphragm structures with electrical resistances approximately one order of magnitude lower than those of asbestos diaphragms.

The new separators make use of composite materials because one material seldom is able to fulfill the many opposing demands simultaneously – for instance, high porosity small thickness, and high mechanical strength. The diaphragm of the H. S. electrolyzer, for instance, is based on polysulfone, a mechanically strong, relatively easily processed, but hydrophobic polymer. In the form of highly porous

sheets it is hydrophilized internally by finely dispersed zirconia, an inorganic oxide of low water solubility. Similarly, porous PTFE sheets can also be hydrophilized by dispersed zirconia.

Quite different and comparably successful is the approach of using nickel net-supported porous ceramics such as NiO or $CaTiO_3$–Ni cermets, yielding mechanically stronger and more robust, yet flexible, diaphragms.

Water Electrolysis with Cation Exchange Membranes (SPE Electrolysis). The aqueous electrolyte may be completely dispensed with by use of a sheet made of proton-loaded water-swollen cation-exchange polymer as electrolyte (the solid polymer electrolyte, SPE, Fig. 45A, also see Fig. 32), which was first introduced by General Electric for fuel cells in space missions (Gemini flights). This fuel-cell option has successfully been converted into electrolyzer technology and offers a promising solution for small electrolyzers: any dangers and difficulties involved in handling hot concentrated caustic alkali solutions are avoided.

Figure 45. Nonconventional electrolyzers
A) Solid polymer electrolyte (SPE) electrolyzers decomposing deionized water at ca. 100 °C; B) Steam electrolyzers with zirconia electrolyte decomposing water vapor at 800–900 °C

The electrodes are formed within the outer layers of Nafion membranes by interdiffusing two solutions, one containing salts of the platinum group metals, the other an appropriate reducing agent, and precipitating in situ a coherent highly porous catalyst layer on either side of the membrane. The primary electrode deposits are then reinforced by further metal deposition. Current is transmitted through porous plates (platinized titanium anodes and carbon cathodes) and dense bipolar metal sheets. The porous metal plates permit simultaneous feeding of the highly purified water to be decomposed and removal of the evolved gases. Fig. 46 compares the current voltage curve for the solid polymer electrolyte electrolyzer with that of advanced alkaline electrolyzers and the steam electrolyzer. Typically, SPE electrolyzers are operated at current densities around 1 A/cm^2. At lower current densities, current efficiencies decrease substantially below 100 % because of counterdiffusion of the generated gases through the < 50-µm ion-exchange membrane.

Figure 46. Comparison of current – voltage curves of solid polymer electrolyte, advanced alkaline, and steam electrolyzers

High-temperature Steam Electrolysis. The ionic conductivity of zirconia, which between 800 and 900 °C becomes comparable to that of 10^{-1} M aqueous electrolyte solutions at ambient temperature, permits high-temperature steam electrolysis. This technique is particularly appealing because the decomposition voltage, as calculated from $\Delta G°$, decreases as the temperature increases and drops to a value of only 0.9 V around 850 °C. The cell scheme (Fig. 45B) resembles the SPE cell. The cathodes are made of nickel cermet and the anodes consist of semiconducting Mn-containing perovskite layers. Although much effort has gone into the development of this electrolyzer, which is realized in the form of small cylindrical elements of 1 cm × 1 cm size, the technique is still far from competitive with conventional or advanced alkaline water electrolysis. The operating cell voltage of 1.3 – 1.4 V is still far from the theoretical 0.9 V, and quite a number of material problems are also unsolved. In particular, the thickness of the electrolyte is still too high, so that the internal

resistance of the cell does not permit current densities of more than a few hundred milliamperes per square centimeter. It might be possible that the development of solid oxide fuel cells leads to substantial improvements of steam electrolysis. At present, SPE and steam electrolysis are not commercially available.

4.3. Anodic Generation of Peroxodisulfuric Acid and Peroxodisulfates

Peroxodisulfuric acid and its salts – in contrast to the salts of most other inorganic peroxo acids, which are prepared chemically – are produced exclusively by anodic oxidation of aqueous sulfuric acid solutions:

$$2\,SO_4^{2-} \longrightarrow S_2O_8^{2-} + 2\,e^-$$

Preconditions for attaining high current yields in this process are the use of high concentrations of sulfuric acid (ca. 500 g H_2SO_4 per liter), high current densities (0.5 – 0.7 A/cm^2), low process temperature (18 – 20 °C), the addition of O_2-evolution inhibitors such as F^- anions, and the use of smooth platinum anodes, which favor adsorption of SO_4^{2-} anions. Reduction of the product is prevented by porous coatings on the cathode, which build up a diffusion barrier for peroxodisulfate anions.

Potassium, sodium, and ammonium peroxodisulfates are prepared with similar electrolysis technology from solution of the alkali-metal or ammonium sulfates and sulfuric acid (→ Peroxo Compounds, Inorganic).

4.4. Electrowinning and Electrorefining of Metals

4.4.1. Aqueous Electrolytes

Pyrometallurgical winning of metals is less expensive by far than electrowinning of metals by cathodic deposition from aqueous solution. But the pyrometallurgical processes have slight or only partial purification effects and yield impure metals that do not satisfy quality standards. Therefore, electrowinning and electrorefining have become important for the production of high-quality copper, zinc, lead, nickel, and cobalt. Electrorefining is based on the potential series of metals [181]. Anodic dissolution of impure metals if the current densities are small and therefore the overpotential negligible leaves the noble components of raw, unrefined metals undissolved. These noble components precipitate in the so-called anode slime or sludge, whereas the metals that are less noble than the metal being electrorefined dissolve with the main metal but are not redeposited on the cathode. Therefore, the less noble metals accumulate in the aqueous electrolyte. For any two metals M_1 with standard electrode potential E_1^0 and M_2 with E_2^0, the voltage difference $(E_1^0 - E_2^0)$ establishes the anodic dissolution equilibrium and defines the concentrations c_1 and c_2 of the two metal ions in equilibrium at a given electrode potential E according to the Nernst equation

$$E = E_1^0 + (RT/z_1 F)\ln c_1 = E_2^0 + (RT/z_2 F)\ln c_2$$

$$\frac{(c_1)^{1/z_1}}{(c_2)^{1/z_2}} = \exp\left\{-\frac{F\left(E_1^0 - E_2^0\right)}{RT}\right\}$$

The second equation neglects the activity coefficients of the metals and is applicable only if electrochemical dissolution/deposition is a fast process for both metals. This is the case for the metals Cu, Zn, and Pb but not for Ni, Co, and Fe. The deposition/dissolution of nickel is particularly sluggish, which diminishes the efficiency of an electrorefining process involving nickel because enhanced overpotentials are generated at both the anode and the cathode.

Alloy formation, which may change the chemical activity of the minor components greatly, is also not allowed for in the equation. For instance, zinc alloyed in nickel ultimately codeposits with nickel, although according to the difference in standard electrode potentials, $E_{Ni}^0 - E_{Zn}^0 = 0.53\,V$,

the equilibrium concentration of the two ions should differ by a factor of 10^9. However, zinc becomes much more noble upon alloying.

Such effects and the accumulation of impurities in the recirculated electrolyte make chemical treatment and purification of the electrolyte indispensable for all electrowinning and electrorefining processes. Since electrowinning with insoluble anodes starts from cruder materials than electrorefining, the chemical purification of

the electrolyte must be even more elaborate and expensive for electrowinning than for electrorefining.

Therefore, the important purification steps for electrowinning of nonnoble metals, like zinc, are hydrometallurgical rather than electrochemical. This is exemplified by the flow sheet in Fig. 47. The process begins with roasted galena, which is leached with recirculated electrolyte (cell acid). The silver and lead remain in the sludge. All elements nobler than zinc are then precipitated by cementation with zinc dust, and the cemented sludge is treated further to recover Cd, Ni, Co, and Fe. Iron can disturb zinc electrowinning seriously by electrochemical short circuiting:

$$\text{Cathode } Fe^{3+} + e^- \longrightarrow Fe^{2+}$$
$$\text{Anode } Fe^{2+} \longrightarrow Fe^{3+} + e^-$$

Therefore, iron(III) ions are precipitated as jarosite, a crystalline iron(III) sulfate oxide hydrate of extremely low solubility. As a second example, in copper refining accumulated nickel and other contaminants must be removed in a bleed stream.

Figure 47. Flow sheet of the jarosite process [182]

For electrowinning and electrorefining of metals, mass transfer towards the cathode is of supreme importance. Convective diffusion driven by free (only gravity) convection caused by depletion of the solution at the cathode dominates mass transfer in these electrolysis processes. Anodes and cathodes, typically $0.8 \times 1.2\,m^2$, are suspended vertically at a distance around 10 cm from each other. They are arranged alternately one after the other in large rectangular tanks, which contain several hundred electrodes. Although there is a steady flow of electrolyte from one end of these huge tanks to the other, the flow velocity is small and electrolyte flow is not directed parallel to the electrode surface and thus does not contribute to convective mass transfer towards the electrodes to a significant degree.

The electrolyte for copper electrorefining contains ca. 40 g of Cu per liter (a concentration somewhat less than 1 M) and total depletion of copper from the solution decreases the density by several grams per 100 mL, i.e., by several percent. The Grashof number under these conditions

$$Gr = \left(x^3 g \Delta\varrho / \varrho\right) / \nu^2$$

would exceed the critical value of 10^{15} for x, the distance from the lower edge of the cathode, where the electrolyte is depleted of Cu^{2+} ions by electrodeposition of copper for turbulence; this distance x exceeds several centimeters. Therefore, for the greater part of the cathode length, usually of the order of 1 m, turbulent flow, with correspondingly intense mass transfer, prevails. But since mean mass-transfer coefficients do not exceed ca. 10^{-3} cm/s, mean current densities for cathodic metal deposition in electrowinning and electrorefining processes must be kept low, on the order of $200\,mA/cm^2$, to stay well below mass-transfer-limited current densities. Higher current densities cause the quality of the deposited metal to deteriorate: the deposit becomes coarse, forms whiskers, and begins to occlude or incorporate electrolyte, floating anode slime, and other impurities.

Even at current densities significantly lower than mass-transfer-limited values, deposit quality must be improved with surfactants. These additives increase the crystallization overpotentials for the deposited metal – inducing frequent nucleation, which gives rise to smooth cathode surfaces with little inclusion of foreign substances. Such surfactants are absolutely neces-

sary for obtaining highly purified metals and preventing the formation of dendrites, which can short-circuit the cell. Cheap, widely used additives are animal glue (gelatin), lignin sulfonates, and aloe extract, the last mainly polyphenols. All these additives are continuously consumed because of hydrolysis, oxidation by air, and adsorptive incorporation into the deposited metal and the anode slime.

Anodes for electrowinning processes are conventionally made of lead with few percent of silver. They have remarkably high oxygen-evolution overpotentials. In the future, activated titanium anodes will become more important.

Unlike all other electrochemical and chemical processes, the cost factor labor is extraordinarily high for electrowinning and electrorefining of metals because of the frequent electrode handling. In a process with anode lives of ca. 30 days (Cu, Ni) or only 10 – 14 days (Pb), and even shorter life spans for cathodes, there is the constant necessity of anode casting and the exchange of anodes and cathodes. Continuous progress in automatization is vital for the survival of these processes.

Aside from the labor costs, the cost structure of these processes are unique because of the investment costs for solution processing and the electrolyzer tank house and the capital required for the metal inventory in electrodes and circulated electrolytes.

Copper Electrowinning and Electrorefining. Copper [*7440-50-8*] is almost always electrorefined, less frequently electrowon. The raw material is the raw copper obtained by reduction of the oxidic ores or concentrates with carbon in a blast furnace. Raw copper is cast into anodes containing roughly 98 % Cu, the rest being mainly nickel and lead, with a fraction of a percent of noble metals, especially silver.

Table 8 summarizes the operational conditions. Nickel sulfate removal is accomplished in a bleed stream from which copper is electrowon prior to evaporation and crystallization of $NiSO_4$. The removal of Cu in *liberator cells* serves to balance the copper content of the bath and offset the additional chemical dissolution of copper due to oxidation by dissolved oxygen, which otherwise tends to increase the Cu^{2+} content of the electrolyte steadily (→ Copper, Chap. 6.2.).

Figure 48. Hybinette cell for nickel electrowinning [182], [183]
a) Anode; b) Cell wall; c) Cathode; d) Diaphragm; e) Catholyte inlet; f) Anolyte exit

The cost contribution of electrical energy is an insignificant fraction of the whole process cost. Therefore, increasing the space – time yield is of special concern. Increasing the current density by at least 50 % by periodic current reversal is one approach now being used. The current is reversed for 10 s out of every 200 s, and correspondingly 5 % of the deposited copper is redissolved. This causes electropolishing, which produces high-quality, smooth deposits at high current densities. Another approach (Onahama refinery, Japan) consists of casting thinner anodes, which reduces the copper inventory by 50 %, and increases the space – time yield by ca. 20 % because the electrodes can be spaced closer together without short-circuiting. However, labor costs are increased by this measure, as does the amount of recycled anode scrap.

Electrowinning of copper is not fundamentally different from electrorefining, except that the depleted electrolyte is recirculated to leach copper ores. Purification is today mainly based on solvent extraction. The current densities can be greater for electrowinning because the stirring by the oxygen evolved at the anode enhances bath convection and mass transfer.

For more details see → Copper.

Table 8. Typical energy requirements in electrorefining and electrowinning

	Copper		Nickel refining		Zinc
	Refining	Winning	Metal anode	Sulfide anode	electrowinning
Current density, mA/cm^2	210	300	200	200	570
Current efficiency, %	97	85	96	96	90
Cell voltage, mV	280	2000	1900	3700	3500
Reversible cell voltage	0	900	0	350	2000
Cathodic overpotential	80	50	250	1500	150
Anodic overpotential	30	600	300	250	600
Ohmic voltage drops	100	400	1050 *	1250 *	500
Cell hardware IR	70	500	300	350	250
Electric energy requirement, kW h/kg	0.25	2	1.9	3.5	3.3

* With diaphragm.

Nickel Electrowinning. Nickel [*7440-02-0*] electrowinning begins with either crude nickel or nickel matte (Ni_2S_3) anodes [182, p. 357 ff]. In both cases the metallic contaminants to be removed are the same: mainly copper, cobalt, and iron. In both cases the anolyte must not be allowed to enter the cathode chamber prior to purification. In the Hybinette cell (Fig. 48), the cathodes are surrounded by a cathode bag. The depleted catholyte flows out of the cathode bag into the anode chamber because of a small hydrostatic head. In the anode chamber, nickel ions pass into the electrolyte:

$$Ni \longrightarrow Ni^{2+} + 2e^-$$

or

$$Ni_2S_3 \longrightarrow 2\,Ni^{2+} + 3S + 4e^-$$

Then the recycled electrolyte is purified. Copper(II) is extracted by cementation with nickel powder, and iron and cobalt are precipitated together with lead by oxidation with chlorine and addition of basic $NiCO_3$. If nickel matte is the starting material, purified sulfur is recovered from the anode sludge. The operational conditions for both processes are shown in Table 8. Starting from nickel matte, rather than raw nickel, requires higher cell voltages, much higher than would be expected from the difference between the two standard electrode potentials, which differ by only ca. 0.3 V. This much higher cell voltage is caused by electrode kinetic hindrance and additional ohmic potential drop on account of an adherent porous layer of sulfur that covers the anode.

For more details see → Nickel.

Zinc Electrowinning. The chemical purification procedures involved in electrowinning zinc [*7440-66-6*] were discussed, as an example, at the beginning of this section. The peculiar circumstance of zinc electrowinning is the negative standard electrode potential of zinc (− 0.76 V), which would make zinc deposition impossible except for the fact that hydrogen evolution at zinc cathodes has a very high overpotential ($j_0 = 10^{-11}$ A/cm^2). Nevertheless, care must be taken to keep the current efficiency for zinc deposition as high as ca. 90 %. The process is carried out at the rather low temperature of 35 °C. Ten percent of the current goes into hydrogen evolution, which improves mass transfer enough that current densities can exceed 0.5 A/cm^2. The operational conditions for zinc electrowinning are listed in Table 8 [182, p. 363 ff].

For more details see → Zinc.

Lead Electrorefining. The electrorefining of lead [*7439-92-1*], introduced in 1903 as the Betts process, is especially effective in separating bismuth, which goes into the anode sludge. Chemical treatment of bullion is used to remove copper, and subsequently tin (together with As, Sb, and Bi) by precipitation with caustic soda. The crude anodes consist of (wt %) ca. 98 % Pb, 0.5 % Bi, 0.01 % As, 1 % Sb, 0.02 % Cu, and 0.02 % Sn. The electrorefining process uses either hexafluorosilicic acid (H_2SiF_6) or sulfamic acid (HSO_3NH_2) as

the electrolyte. Current densities are somewhat higher for the processes working with H_2SiF_6 (160 – 200 mA/cm^2) than for the sulfamic acid process (120 – 160 mA/cm^2). In both cases a relatively low temperature is maintained to retard hydrolysis of the electrolyte [182, p. 356 ff].

For more details see → Lead.

4.4.2. Melts

Manganese ($E^0 = -1.05$ V) is the most reactive metal that can be electrodeposited from aqueous solution. Metals even more reactive – aluminum, magnesium, and the lanthanides – are electrodeposited from salt melts. Cathodic hydrogen evolution, due to water decomposition, cannot interfere with cathodic metal deposition. Normally melt electrolysis is not used as a purification step because of the difficulty of purifying and recycling contaminated melts. A thoroughly purified oxide is the starting material for electrowinning. The Bayer process, for instance, is an integrated step in aluminum production since it produces aluminum oxide of very high purity (impurities < 0.1 wt %) from crude bauxite. The Bayer process is responsible for 40 – 50 % of the production cost of aluminum [184, p. 296].

Typical problems posed by melt electrolysis are first of all material problems: the *stability* of (1) cell linings against chemical attack of the usually agressive melt, (2) anodes against the corrosiveness of the anode gases (Cl_2, O_2), and (3) cathode material against reaction with the liquid metal. These three problems are especially severe because of the high process temperature, usually above the melting point of the metal: 660 °C (Al), 648 °C (Mg), and 97 °C (Na).

A second typical problem is dispersion or dissolution of the liquid metal into the electrolyte, which allows partial reoxidation due to convective transport of the metal mists toward the anode. There the metal reacts with evolved gas, or it is directly reoxidized at the anode. This phenomenon is caused by (1) the low surface tension of molten metals in contact with the molten electrolyte, (2) the relatively small density differences between molten metal and molten salt, and (3) strong convection due to magnetohydrodynamic effects and gas stirring. Cell geometry must be designed to suppress excessive convection or to provide a sufficiently large interelectrode gap (ca. 8 cm in aluminum smelters) to minimize metal reoxidation.

A further engineering aspect that is unique and typical for all high-temperature electrolytic processes is the careful calculation of heat balances and heat isolation devices for electrolyzers and potlines, which is indispensable for energy conservation and for steady, reliable operation of molten-salt electrolyzers over months and years.

Aluminum Production [184, 185, 186].
The electrolytic production of aluminum [*7429-90-5*] by electrolysis of Al_2O_3 dissolved in cryolite (Hall–Héroult process) is by far the most important electrochemical process based on the use of a molten-salt electrolyte.

$$Al_2O_3 + 3\,C \xrightarrow{6F} 2\,Al + 3\,CO$$

Six faradays of electricity are required for each mole of Al_2O_3.

The addition of Al_2O_3 to cryolite (*mp* ca. 1000 °C) decreases the melting point as the alumina content is increased up to 10 wt %, where the eutectic melts at 960 °C [186].

Figure 49 depicts the construction of a modern Hall–Héroult cell schematically. The cell is composed of an outer carbon or graphite lining and a row of adjustable prebaked carbon anodes. At the bottom of the pot there is the cathode, a pool of liquid aluminum, which is emptied periodically by suction and which is covered by the molten electrolyte into which are immersed the gas-evolving anodes. The melt is covered by a crust of solid electrolyte and a supply of fresh, loose Al_2O_3. Periodically crushing this crust serves to replenish the Al_2O_3 content of the bath. The cathodic reaction consists of reducing fluoro-oxo-aluminum complexes:

$$AlOF^{(n-1)}{}_n{}^- + 3\,e^- \longrightarrow Al + O^{2-} + nF^-$$

A mixture of carbon monoxide and carbon dioxide is evolved at the anode: the depolarizing carbonaceous anode material reacts with the anodically generated oxygen,

$$(x+y)\,C + (x+2y)\,O^{2-} \longrightarrow x\,CO + y\,CO_2 + (2x+4y)\,e^-$$

In accord with this anode reaction, the Hall – Héroult process consumes significant amounts

of extra energy due to the consumption of the carbon anode.

There is violent stirring of the molten metal and the electrolyte due to magnetohydrodynamic effects and anodic gas evolution. Vigorous stirring may cause severe losses in current yields and energy efficiency. The reoxidation of metal mists at the anode or the reoxidation of the dispersed metal by the anode gases causes a loss of energy. These energy losses are avoided to a certain extent by increasing the anode – cathode distance. Aluminum smelters operated with optimal interelectrode distances of a little less than 8 cm achieve current efficiencies exceeding 93 % and electrical energy consumptions of optimally 13 kW h/kg (theory: 6.34 kW h/kg). The relatively low energy efficiency of the Hall–Héroult process is the reason more energy-efficient electrolysis processes have been sought.

Figure 49. Hall – Héroult cell

In 1954, Alcoa resumed the work of Bunsen [187], who was the first to produce aluminum metal by electrolysis of alkali chloride – aluminum chloride melts. Alcoa developed the technology of aluminum deposition from alkali chloride – aluminum chloride melts up to a commercial scale. The Alcoa electrolyzer uses stacks of bipolar carbon electrodes. The upper parts serve as cathodes, and the lower grooved parts serve as chlorineevolving anodes. This electrolyzer is reported to produce aluminum metal with a specific energy demand of 10 kW h/kg, offering a 30 % saving in electrical energy over the Hall–Héroult process. In LiCl melts of low $AlCl_3$ content the energy savings seem to be still more promising [188]. However, further development of chloride electrolysis technology also requires the development of a commercially attractive route for $AlCl_3$ production from bauxite [188]. However, the Alcoa process eventually failed, because the anodically generated chlorine was contaminated with perchlorinated aromatic compounds which could not be eliminated at reasonable costs.

For more details on aluminum production, especially the Hall–Héroult process, see → Aluminum.

Magnesium and Alkali Metal Production. Figure 50 shows the decomposition potentials of the alkali-metal chlorides as functions of temperature. Magnesium chloride, with a decomposition voltage of 2.6 V at 700 °C is the most easily decomposed chloride among the Group 1 and 2 chlorides.

Figure 50. The decomposition potentials of the alkali-metal chlorides as functions of temperature [189]

The light alkali metals and alkaline-earth metals magnesium, lithium, sodium, and potassium have lower densities than the melts of their chlorides. Therefore, the electrodeposited metals ascend through and collect on top of the chloride melts. They must be prevented from coming into contact with the electrogenerated chlorine.

Interelectrodic gaps of several centimeters together with steel diaphragms between the electrodes and steel collectors that gather the ascending metal droplets above the cathode allow effective separation of chlorine and liquid metal – but at the expense of relatively high cell voltages and relatively low energy efficiencies. Nevertheless, metal dispersion and the solubility of metal in the melt are reasons for low current efficiency (Table 9). The trade-off between high current efficiency and low cell voltage results in energy

yields between 30 % and 40 %, which are typical for salt-melt electrolysis but which are low compared to large-scale electrolysis processes with aqueous solutions.

Table 9. Working temperatures, cell voltages, and current efficiencies in the production of light alkali metals and alkaline-earth metals

Cell operating characteristics	Metal		
	Lithium	Sodium	Magnesium
Working temperature, °C	400 – 420	590 – 600	660 – 670
Cell voltage, V	8 – 9	6.5 – 7	5.5 – 6
Current efficiency, %	85 – 90	90 – 95	78 – 80

For more details see → Lithium and Lithium Compounds, → Magnesium, → Potassium and Potassium Alloys, and → Sodium and Sodium Alloys.

4.5. Electrochemical Processes in Nuclear Fuel Reprocessing

Oxide fuel light water reactors (LWR) are dominant for nuclear electricity production worldwide. For this type of fuel an aqueous medium process to recover the fissionable material is well established. The zirconium alloy-clad fuel elements containing uranium oxide – plutonium oxide fuel are cut up, and the uranium and plutonium are leached out of the cladding material with nitric acid. Afterwards the solution is purified by multiple extractions using *n*-tributylphosphate (TBP) diluted with kerosene (→ Nuclear Technology, Chap. 5.4.1.). This process, the Purex process, was first developed in the late 1940s and industrially used in the USA in the early 1950s.

Determined by the demand of the following processes for reenrichment and fuel fabrication to minimize shielding and to facilitate the handling of the refabricated fuel elements, it is a particular requirement for the reprocessing process to guarantee an extreme product purity and to keep the contents of radioactive contaminants as low as possible. The permissible contamination limit for the long lived fission product cesium, after reprocessing, is, for example, about 3 µg/kg and the residual content for plutonium is limited to about 15 µg/kg in the uranium product. Furthermore, the process calls for a high product yield of 99 %. For the extraction process about 99.5 % is achievable in a modern plant. On average, this corresponds to a content of about 1 mg/kg plutonium in the extraction raffinates.

Another requirement of commercial reprocessing is minimization of the radioactive waste volume in order to reduce costs. The costs of radioactive waste treatment and storage are incomparably higher than the actual costs for conventional chemical wastes. The major part, more than 50 % of reprocessing costs are capital costs. This is the reason why current R&D activities are directed to a cost reduction by a simplification of the process.

Figure 51 shows a schematic diagram of the Purex process (see also → Nuclear Technology, Chap. 5.4.1.7.). Five extraction cycles are used to meet the product specifications. In the first high-active cycle the major portion of fission products is separated from uranium and plutonium. A radioactivity portion of about 10^{-5} of the 'nonproblematic' fission products and actinides (alkali, alkaline-earth, rare earth, transplutonium elements, etc.) leave this cycle with the products uranium and plutonium. The products are separated later by reducing tetravalent plutonium to Pu(III) which has a very low distribution coefficient and is backextracted into an aqueous phase. Between each cycle plutonium has to be reoxidized and hydrazine, which is necessary to stabilize plutonium in the trivalent state, must be destroyed by oxidation.

One reason for incomplete separation is the degradation of the solvent by radiolysis and hydrolysis [190]. Some fission products and plutonium form complexes with the TBP degradation products. Thus the degradation products must be removed by an alkaline wash.

Both laboratory and industrial experiences with the conventionally designed high-active first Purex cycle show that the product purity specifications cannot be met, even for the 'nonproblematic' fission products [191]. Therefore, two additional refining cycles are used for each product, uranium and plutonium (see Fig. 51).

4.5.1. Electroredox Separation Processes

In order to separate uranium from plutonium, Pu(IV) is reduced to virtually inex-

Figure 51. Schematic diagram of the PUREX process
The jagged arrow indicates an electrochemical process.

tractable Pu(III). For the reduction of plutonium, four processes have been developed to technical maturity with the following four reductants: iron(II)sulfamate [192], uranium(IV)nitrate [193], hydroxylammonium nitrate [194], and electroreduction within the extractor [195]. Generally U(IV) is added as a reducing agent during extraction according to the following equation

$$2\,Pu^{4+} + U^{4+} + 2\,H_2O \longrightarrow 2\,Pu^{3+} + UO_2^{2+} + 4\,H^+$$

The external feed U(IV) process, which is usually applied in current industrial reprocessing has at least two drawbacks: (a) demand for a high U(IV) excess, and (b) occasionally failure of the process caused by the autocatalytic reoxidation of Pu(III) and U(IV) starting in the organic phase.

These facts initiated activities in different countries to develop the in situ *electroreduction* process [196, 197, 198, 199]. A comparison of the chemical process with the electrochemical process was made in [200] and resulted in a preference for the electroreduction process. Compared with chemical separation processes for Pu, electroreduction is simpler from both engineering and operational points of view. The process has all the advantages of the externally fed U(IV) process but avoids its drawbacks.

Because of its simplicity and compactness, also *electrooxidation* has significant advantages when compared to the chemical oxidation process.

Titanium, platinum, and hafnium show sufficiently low corrosion rates to guarantee a long life-time of the electroredox equipment. Since the first electroreduction experiments performed

at Forschungszentrum Karlsruhe, efforts to design simple, compact and reliable electroredox equipment for industrial applications led to the following three design criteria [195]: (a) no diaphragm, (b) casing of apparatus used as cathode, and (c) operation at constant current or voltage.

Basic chemical investigations and corrosion tests of different materials showed that these criteria can be fulfilled for both the electroreduction extractors and the electrooxidation cell [195], [201]. Diaphragms are not necessary because of the irreversible character of the U(VI) electroreduction in the used electrolyte [202] and of the hydrazine electrooxidation. Titanium was found to be well suited as the container and cathode material, having corrosion rates of less than 50 µm per year under process conditions. Experiments with constant current or voltage operation showed that side-reactions such as hydrogen formation and nitrate reduction can be suppressed to a tolerable level, so that reference electrodes are not required for constant voltage operation.

4.5.2. Electroreduction Processes

In the electroreduction processes plutonium is reduced by electrolysis at the cathode

$$Pu^{4+} + e^- \longrightarrow Pu^{3+} \quad 0.92\,V$$

and by U(IV) generated in-situ.

The local uranium : plutonium ratio in the extractor determines which reaction is dominant. The Pu(III) is reoxidized in both phases by nitrite in an autocatalytic reaction [205]:

$$Pu^{3+} + HNO_2 + H^+ \longrightarrow Pu^{4+} + NO + H_2O$$

For this reason, the aqueous phase is stabilized with hydrazine, which reacts with nitrous acid

$$N_2H_5^+ + HNO_2 \longrightarrow HN_3 + 2\,H_2O + H^+$$
$$N_2H_5^+ + 2\,HNO_2 \longrightarrow N_2 + N_2O + 3\,H_2O + H^+$$

Since hydrazine is not extractable, a part of the Pu(III) is oxidized by organic nitrite, which results in an excessive U(IV) consumption, [214].

$$N_2 + 5\,H^+ + 4\,e^- - N_2H_5^+ \quad -0.23\,V$$

Hydrazine itself slowly reduces Pu(IV):

$$4\,Pu^{4+} + N_2H_5^+ \longrightarrow 4\,Pu^{3+} + N_2 + 5\,H^+$$
$$2\,Pu^{4+} + 2\,N_2H_5^+ \longrightarrow 2\,Pu^{3+} + 2\,NH_4^+ + N_2 + 2\,H^+$$

The last reaction is catalyzed by platinum, which is available because of corrosion of the anode [212].

Mixer-Settler. Figure 52 shows schematically the construction of the electroredox mixer-settler developed in Karlsruhe. The mixer-settler is made of titanium and the containment acts as cathode. The anodes are installed in the settler chambers where the electroreduction takes place. The most stable anode material is platinum with corrosion rates of a few micrometers per year. For industrial electroredox equipment, platinized Ta, Ti or other materials are used.

Table 10 summarizes the results of countercurrent experiments with the electroreduction mixer-settlers, called EMMA [195], [204], [205]. The 16-stages MILLI-EMMA was used for uranium-plutonium separation, as well as for plutonium purification, but without a uranium scrub in the latter case. Because of the miniature size of the apparatus, the extraction

Table 10. Results of test runs with electroreduction mixer-settlers

[a] DF = decontamination factor. [b] 9 practical stages for Pu strip, 7 for U scrub. [c] 20 vol % TBP, 30 vol % for all other experiments. [d] 16 practical stages used for Pu strip, without U scrub. [e] 12 practical stages used for Pu strip, without U scrub.

stage efficiency was low, especially in experiments with a high organic to aqueous flow ratio. The major parameter variations were: (a) TBP concentration, (b) plutonium content, (c) current density, (d) HNO_3 concentration in the aqueous strip solution, (e) dibutylphosphoric acid, $(C_4H_9O)_2POOH \cdot$ (HDBP) concentration in the organic solvent, (f) flow ratios, and (g) total volume flow rate (residence time).

The most significant effect on the U/Pu separation was due to variations of the total volume flow rate. A decrease in the total volume flow rate causes complex interactions in the countercurrent extractor due to the increase in residence times for both phases. In the case of the miniature mixer-settler, the increase in extraction stage efficiency seems to be the dominant factor for separation improvement. In the Pu purification experiments an upper limit for the organic to aqueous flow ratio of 3 : 1 was found at Pu product concentrations of about 40 g/L.

The first industrial application was performed in the Pu purification cycle of the Wiederaufarbeitungsanlage Karlsruhe (WAK). The plant was equipped with an electroreduction mixer-settler (WAK-2B-EMMA, 12 stages) and an electrooxidation cell (WAK-2B-ROXI) in 1980 [205], [206]. In addition, in 1984, the first highly active cycle of WAK was equipped with an electroreduction mixer-settler.

In the WAK-2B-EMMA the flow ratio could not be raised above 3 : 1, corresponding to a Pu product concentration of about 36 g/L, although this apparatus has a significantly higher stage efficiency. One reason for the limitation of the Pu decontamination factor (DF) to a maximum of 10^5 are the very long residence times (volume flow limitations for technical reasons) [205], [206].

Pulsed Column. The extractor type preferred today for industrial reprocessing plants are pulsed sieve plate columns (Fig. 53). The main reason for this is the less complicated design of a critically safe pulsed column in comparison to a mixer-settler bank, at least for the U/Pu separation step. The pulsed column is constructed in a similar way to the mixer-settler. The column and the sieve plates, made of titanium, function as the cathode, while the platinized central rod is the anode. In the top decanter of the column, separator shields are installed to promote the separation of electrolytic gas from the organic liquid. The ratio of cathode to anode areas is made as large as possible to reduce anodic reoxidation of Pu(III). To eliminate any risk of a hydrogen explosion, the gas volumes of the mixer-settler and of the top decanter of the pulsed column are sparged with air to dilute the hydrogen below the explosive limit. The hydrogen current yield can be kept below 10 % under typical conditions.

The first experiments with the electroreduction column ELKE done in the plutonium test facility PUTE under the conditions of a Pu purification cycle yielded decontamination factors of up to 10^6 depending on the residual uranium content, flow ratio, nitric acid concentration, etc. [207]. The effective column length was about 8 m. The following experiments were carried out to study the electroreduction feasibility in the first extraction cycle, i.e., for U/Pu separation. Based on the results achieved in the purification cycle a comparable outcome was expected for separation. However, the experiments showed a

surprisingly poor separation efficiency: decontamination factors of only 200 to 2000 were achieved [208]. This was due to the fact that in the middle region of the column unusually large organic phase drops appeared with diameters of up to 20 mm and with inclusions of aqueous phase. This latter effect explained the observed insufficient U/Pu separation by heterogeneous contamination, in this case aqueous drops.

Figure 53. Pulsed electroreduction column
a) Cathode (outer casing); b) Cathode (perforated plates); c) Anode; d) Insulators; e) Gas – liquid separator plates; f) Aqueous-phase inlet; g) Organic-phase outlet; h) Overflow; i) Gas inlet; j) Off-gas outlet

The first way to reduce the amount of entrained aqueous phase transported with the organic phase drops is an increase in pulse energy [209]. The plutonium decontamination factor increases steeply when increasing the pulse energy $A \times f$ (amplitude × frequency) from 90 to 180 cm/min. Applying a pulse energy of $A \times f = 180$ cm/min small organic drops form a homogeneous dispersion without any inclusions of aqueous phase and a maximum Pu-DF of about 12 000 is achieved with a column length of only 5 m for the reductive Pu strip (BX part, see Fig. 51). To meet the final product specification for U, a Pu-DF of about 500 000 is necessary, however. To further increase separation, two consecutive columns were used in order to extend the reductive strip height and to minimize the entrainment effect by the introduction of an intermediate decantation. The results are summarized in Table 11 [209]. Row 2 shows that the desired Pu-DF can be reached with a flow ratio of 7.25 (which is usual in this process step for LWR fuel) by the use of two combined columns with 12.6 m total length.

Furthermore, it was also shown in the experiments, that in the case of a maloperation (interrupted hydrazine feed), no inadmissibly high Pu accumulation appears. The measured maximum plutonium concentration (first column) was always less than 20 g/L within 30 h after interruption in hydrazine supply.

In the electroreduction process only small amounts of the byproducts hydrazoic acid and ammonium are formed, thus reducing the hydrazine consumption. As was demonstrated in the PUTE facility [210], [211], electroreduction has the potential to be operated without the addition of hydrazine, if the nitric acid concentration is kept below 0.7 M within the whole extractor.

4.5.3. Electrooxidation

Between each cycle of the Purex process, plutonium has to be reoxidized to the tetravalent state and hydrazine must be destroyed. For this purpose an electrooxidation cell, called ROXI, was developed (Fig. 54). The anodic destruction of hydrazine is aided by the reactions of hydrazine with Pu(IV) formed by anodic oxidation and with HNO_2, which is cathodically produced in small amounts. The electrooxidation cell is a typical electrochemical flow reactor designed to minimize axial mixing. The electrolytic gas leaves the cell diluted with sparging air. The containment (cathode) is again made of titanium. The anode stacks are made of platinized metal sheets. The major advantage of electrooxidation compared to chemical oxidation with nitrogen oxides is the compactness of the apparatus. The chemical oxidation process requires one absorption column for the complete oxidation of hydrazine and Pu(III) and one additional column to desorb the excess of nitrogen oxides [203].

The yield of the direct anodic oxidation of Pu(III) depends on the nitric acid concentration. Under typical conditions, the major part of the

Table 11. Results of U/Pu separation with two electroreduction columns in series*

7.25	135	180	0.0015	507 000	345
9.33	135	180	0.005	116 000	311

* Org. feed: 88 to 90 g U + Pu per liter, [U]/[Pu] = 100, $[HNO_3] = 0.2$ M, strip solution: $[HNO_3] = 0.1$ M, $[N_2H_5^+] = 0.05$ to 0.15 M, extraction height: BX part: 6.6 m + 6 m, BS part: 1 m, volume flow ratio in BS part: 1, cathodic current density: 0.5 to 0.8 mA/cm^2.

Pu(III) is oxidized autocatalytically by HNO_2. The accompanying U(IV) is consumed by reduction of Pu(IV).

The formation of Pu(VI) is suppressed at a HNO_3 concentration higher than 2 M. The formation of ammonium by cathodic reduction of HNO_3 depends on the electrolyte composition and was measured to be 0.03 to 0.46 mmol $A^{-1}\,h^{-1}$ for an electrolyte without hydrazine [212].

Figure 54. Electro-oxidation cell for plutonium(III) and hydrazine
a) Cathode and housing; b) Anode; c) Gas flow; d) Electrolyte flow; e) Insulation

The average values achieved with the two electrooxidation cells instal1ed in the PUTE facility are given in Table 12. For typical feed compositions, current consumption of about 100 A h per mole $N_2H_5^+$ were measured in the Ti-ROXI. For the Hf-ROXI, a higher current demand was measured, which is probably caused by a smal1er fraction of cathodic reaction supporting the hydrazine destruction. The ammonium formation is low but in some cases still higher than expected. This can be explained by the formation of ammonium in parallel to the electroreduction of HNO_3.

4.5.4. Corrosion

The corrosion of titanium under cathodic conditions depends on the electrolyte composition and on the current density. For the relevant and maximum HNO_3 concentration of 2.5 M, gravimetric experiments show a drastic decrease in corrosion in the presence of reducible cations; no definite effects of current density are detected in this case. Traces analysis in the product solutions confirm this effect for various pieces of equipment. Only a small increase in corrosion is observed at higher ROXI current densities. Thickness measurements of the PUTE-ROXI channel sheets show, after an operation period of 1950 h, comparably small corrosion rates of 23 µm/a even at current densities up to 135 mA/cm^2. The corrosion rate of hafnium, estimated from traces analysis, amounts to 7.7 µm/a at current densities of 50 mA/cm^2.

The anodic corrosion of platinum increases with decreasing nitric acid concentration and with increasing current density and temperature [213]. The corrosion rates obtained by gravimetric, trace and neutron activation analysis for typical electrolyte compositions and current densities amount to a few micrometers per year.

4.6. Electrochemical Water and Effluent Treatment

4.6.1. Cathodic Treatment

Wastewater from different industrial sectors, such as electroplating, photographic development, printed circuit board production, or battery technology, requires special treatment to remove toxic metal ions or to recycle valuable material. Due to increasingly stricter regulations for

the discharge of effluents, the permissible concentration of metal ions in effluents has been strongly decreased in recent years [218, 219, 220]. Table 13 shows the development of the limiting values for different metal ions in Germany from 1983 until 1991 and for comparison the latest values in Switzerland. The concentrations which can be obtained by the conventional technique of hydroxide precipitation are also listed in Table 13. Obviously, the limits for effluent discharge can only be met for a few metals such as Cu or Zn by the conventional technique. Here, the precipitated metal ions are replaced by alkali or alkaline-earth metal ions and in many cases the salt content prevents the recycling and reuse of the water. Furthermore, the cost of disposing sludge containing toxic metals has also been drastically increased during recent years [221]. Costly measures are also necessary to avoid the contamination of ground water with metal ions leached out by the rain.

As an alternative to hydroxide precipitation, ion exchangers are gaining in importance; however, ion exchangers are too costly for many types of effluents, and regenerable exchange resins are not available for all metals. As a result, there is incentive to develop electrochemical processes for pollution control [222, 223, 224, 225, 226, 227, 228, 229, 230].

4.6.1.1. Optimization of Cell Design

Since most of the metal ions can be removed by cathodic deposition, electrochemical processes have been developed, some of which are already commercialized and now being used in the industry [222], [225], [227], [228]. The removal of metal ions Me^{z+} from wastewater is based on cathodic metal deposition:

$$Me_{sol}^{z+} + ze^- \leftrightarrow Me$$

From a thermodynamic point of view, the Nernst equation predicts that it should be possible to decrease the Me^{z+} concentration in solution to an arbitrarily low value, if the potential E of the Me/Me^{z+} electrode is maintained sufficiently negative with respect to the standard potential $E^{o}_{Me/Me^{z+}}$.

$$c_{Me^{z+}} = c^{+} \exp\left[\frac{zF}{RT}\left(E - E^{o}_{Me/Me^{z+}}\right)\right] \quad (23)$$

However, at extremely low concentrations, the rate of the mass transport controlled process strongly decreases. In practice, electrolysis of metals at concentrations below 0.05 ppm (mL/m^3) is no longer economical due to increasing electrolysis time and unacceptably low space — time yield. Since the current densities at low metal ion concentrations are small, the specific energy demand for an electrochemical wastewater purification process is generally

quite low, typically in the order of 0.025 Euro/m^3 [218]. More relevant are the specific investment costs, which are inversely proportional to the space — time yield *STY* of the reactor. For the cathodic metal deposition in an electrochemical reactor of volume V, the space — time yield is defined as the amount of metal dm deposited in a time interval dt:

$$STY = \frac{1}{V}\frac{\mathrm{d}m}{\mathrm{d}t} \tag{24}$$

According to Faraday's law, dm is proportional to the electrolysis charge $A\ \phi^{\mathrm{e}}\ j\ \mathrm{d}t$:

$$\mathrm{d}m = A\phi i \mathrm{d}t \frac{M}{zF} e \tag{25}$$

The optimal process condition are met when the rate of the heterogeneous reaction attains its maximum at the limiting diffusion current density j_{l}. For a given metal ion concentration $c_{\mathrm{Me}^{z+}}$ a high mass transfer coefficient k_{m} and a large specific electrode area are essential to obtain high space — time yields (see Section 3.5).

The reactor performance is not independent of the wastewater properties. Therefore, a normalized space velocity $\varrho_{\mathrm{s}}^{\mathrm{n}}$ was introduced for the characterization of the reactor performance for a given degree of conversion [104], [231]:

$$\varrho_{\mathrm{s}}^{\mathrm{n}} = \frac{I\phi e}{(c_{\mathrm{i}} - c_{\mathrm{e}})\, VzF} \log \frac{c_{\mathrm{i}}}{c_{\mathrm{e}}} \tag{26}$$

This figure gives the volume of wastewater in cubic centimeters treated by reducing the inlet concentration c_{i} by a factor of 10 (c_{e} = 0.1 c_{i}) within 1 s in a reactor volume of 1 cm^3.

4.6.1.2. Electrochemical Reactors and Their Applications

Different types of cell constructions have been designed during recent years. Efficient cell design has been directed towards optimizing the space – time yield, using a high specific electrode area and/or a large mass transport coefficient. With respect to these criteria, the electrochemical cells may be classified into the following three groups [218]:

Improved mass transport and thus increased current density by setting the electrodes in motion or by applying turbulence promoters, but with a relatively small electrode area in a given cell volume. Examples are the pump cell [116], [117] (see Section 3.5) the Chemelec cell [232], the ECO cell [233], [234], the beat rod cell [235], [236] and cells with vibrating electrodes or electrolytes [237].

Attempts to accommodate *large electrode area* in a small cell volume resulted in developments such as the multiple cathode cell [238], the Swiss roll [239], or the extended surface electrolysis (ESE) cells [240].

Improved mass transfer coefficients and enlarged specific electrode area are provided by the use of three-dimensional electrodes. Examples are the porous flow-through cell [241], the RETEC cell [242], the packed-bed cell [243,244,245] the fluidized bed cell [246,247,248,249,250], and the rolling tube cell [251], [252]. Due to the specific fluid dynamic conditions inside these three-dimensional bed electrodes, they provide not only large specific electrode areas but also high mass transport coefficients.

Chemelec Cell. The Chemelec cell (manufactured by Bewt Water Engineers Ltd., Alcaster, UK), depicted schematically in Figure 55 uses a fluidized bed of glass spheres as turbulence promoters to improve the mass transfer to the electrodes consisting of a series of closely spaced gauze or expanded metal sheet electrodes. [232], [253]. Since the electrolyte flow velocity must exceed the minimum fluidization velocity, the residence time and the degree of conversion per pass are limited. Therefore, this cell is suitable for pretreatment or recycling operation and is commonly used in the electroplating industry for maintaining a moderate metal ion concentration of approx. 50 ppm in a recirculated wash water of a rinsing tank.

Cells with Rotating Cylinder Electrodes. High mass transport coefficients are also achieved in cells with rotating cylinder electrodes (RCE), and a small gap between the cylindrical cathode and anode. High rates of mass transport are experienced in the turbulent flow regime, so that RCE reactors allow metal deposition processes to take place at high speeds, even from dilute solutions. RCE reactors have been operated at diameters from 5 – 100 cm, with rotation speeds from 100 – 1500 rpm and currents

Figure 55. The Chemelec cell, with inert fluidized bed

Figure 56. The ECO-cell cascade

from 1 A to 10 kA [254]. It is possible to design RCE reactors with scrapping devices to remove the deposited metal continuously in powder form from the cathode surface.

The *ECO cell* (Fig. 56) designed in the U.K., has already been produced and applied industrially. The cell usually has a segmented elctrolyte chamber (Fig. 56) to improve the residence time distribution by cascading. It has been used to recover silver and copper from wastewaters. The copper concentration in an 8-m^3/h effluent stream, passed over a 1.7-m^2 electrode, is reduced from 100 ppm to 2 ppm with a current of 1000 A at a current efficiency of 65 %. In this case, the power consumption per 1 m^3 of wastewater is 4.5 kW h, including the electrical energy necessary for electrode rotation.

Beat Rod Cell. The *beat rod cell* [251], [252], which is mainly used in small electroplating shops, is shown in Figure 57. Metal rods mounted into a rotating cylindrical carrier act as cathodes. Because of the rotation of the carrier, these rods beat against one another, causing mechanical release of metal, which can be collected as a powder at the bottom of the cell. Such a cell can reduce the silver content of a cyanide solution from 7.05 g/L to 3.5 mg/L in a batch operation mode.

Swiss Roll Cell. An efficient way of fitting a large planar electrode area in a small volume is the design of the Swiss roll cell, (see Fig. 29, Section 3.5). When the cell is filled with deposited metal, it is regenerated by treatment with acid, similar to common ion exchanger resins. Large space – time yields are realized and mass transport conditions are favorable since the separator functions as a turbulence promoter. The capacity of the cell can be further increased by using perforated electrodes, thus achieving a truly three-dimensional electrode structure. Mesh electrodes wrapped around a perforated winding core, lead to another version of the Swiss roll cell with radial flow.

ESE Cells. Another design which uses mesh electrodes instead of foils is known as ESE cells. These cells have been successfully applied on an industrial scale for the purification of copper containing effluents. A quite efficient commercial system for wastewater treatment is the *RETEC cell* (Eltech System Corp., Cardon, Ohio). The design is similar to a simple tank house cell, but contains 6 – 50 three-dimensional cathodes constructed as flow-through metal sponge electrodes [242]. These cathodes have an active surface area of approximately 15 times their geometrical area. Between each pair of cathodes is placed an inert, dimensionally stable anode (DAS) which is an oxide-coated titanium mesh. The cell is used in closed water recycling systems in the electroplating industry with applications similar to those of the Chemelec cell.

Packed-bed cells with three-dimensional electrodes are obtained when using electrodes consisting of electron conducting particulate material through which the electrolyte can flow. Numerous versions of these porous cells have

Table 14. Applications of the enViro cell [219]

been described in the literature [227], [228], [241], [255,256,257] (see Section 3.6. In a three-dimensional electrode the penetration depth of the current is restricted in the direction parallel to current flow. According to Equation (22), see Section 3.6, the penetration depth of the limiting current density increases as the concentration, which is proportional to j_l, decreases. The application of this principle led to the *enViro cell.* shown in Figure 58, which can operate satisfactorily at low metal ion concentrations. For example, in a single-pass operation, the concentration can be reduced from 10 – 50 mL/m^3 to less than 1 mL/m^3. This cell has a high space–time yield at a residence time of a few minutes only. The metal ion concentration can be reduced by up to a factor of 1/1000 in a single pass. The enViro cell has found wide spread industrial application (see Table 14).

Fluidized-Bed Electrolysis. The principle of fluidized bed electrolysis originates from FLEISCHMANN and GOODRIDGE [247]. The electrolyte flows from bottom to top through a loose bed of particles (Fig. 59). The advantage is that the particles are held in suspension, thus avoiding bed blockage as found in fixed-bed cathodes and allowing continuous metal recovery. The fluidized particles are cathodically charged via a feeder electrode. The growing particles are gathering at the lower part of the cell where they can be collected and replaced by fresh particles from the top. Because the height of the cell is restricted to about 2 m for hydraulic reasons and the fluidization velocity has to be maintained at a relatively high level, short residence times and thus only limited degree of conversion per pass can be achieved. Continuous operation with solution recirculation and cascade arrangements of cells are therefore used in practical applications. Fluidized-bed electrolysis has been examined for different applications in many laboratories, [133], [134], [155], [246], [255], [256] and has also been applied on an industrial scale for metal recovery [249], [250]. A typical example is the removal of copper from the process liquor in cellulose acetate production for membrane fabrication of artificial kidneys [218].

Figure 58. The enViro cell

Figure 59. Fluidized-bed electrolysis according to FLEISCHMANN and GOODRIDGE

Moving and Circulating Bed Electrodes [257]. Figure 60 shows an example of the *rolling tube cell* [251], [252]. In principle this cell resembles the one used in the well-known plating process for piece-goods, using slowly rotating barrels. The rotating drum is only partially filled with graphite particles to achieve thorough agitation. The cathode has the shape of a perforated annular-type drum and is surrounded inside and outside by anodes to render the current distribution as homogeneous as possible. This cell is especially useful for silver and gold recovery. Further developments of moving bed cells and their application can be found in [258]. Utilization of the spouted bed, vortex bed, and moving bed electrodes for copper recovery from dilute solutions has been described in [257].

Cementation Processes. [259, 260, 261, 262]. An alternative to electrically driven cells using high surface area electrodes such as packed or fluidized-bed electrodes is a cementation system where electrochemical activity takes place spontaneously and a more noble metal may be deposited onto a less noble substrate which itself progressively dissolves [259]. Thus, no electrical energy is consumed in the precipitation reaction although power is required for electrolyte circulation. Well known examples of commercial cementation processes are the final purification step in leach liquor treatment prior to electrolysis in zinc electrowinning, where zinc dust is used as precipitant, and the recovery of silver from spent photographic solutions using steel substrates.

4.6.1.3. Operation Data of Electrochemical Cells

A summary of operation data of the different reactors and cell design described above is given in Table 15. Since these data are obtained from cells of different size and different process conditions, they give a rough guide rather than a reliable basis for assessing the individual reactors [218].

The data presented in Table 16, i.e., the specific electric energy demand and the normalized space velocity, are closely related to the eco-

Figure 60. Rolling tube cell

Fluidized-bed cell	0.27		30
Rolling tube cell	14.2		0.4

nomic efficiency [218], [220]. The specific electric energy consumption E_s^e for the treatment of 1 m^3 of effluent is relevant for the calculation of the energy costs. For cells containing rotating parts, the total energy consumption E_s^t is also specified. Considering both the specific electrical energy consumption and the normalized space velocity of processes which have already found industrial application, the packed-bed and fluidized-bed electrolysis seem to perform best.

4.6.2. Electrodialysis

For desalination or removal of ionic pollutants from aqueous wastewaters, electrodialysis is also useful [263, 264, 265, 266, 267, 268, 269]. The scheme for recovery of nickel salts from electroplating rinsing waters is shown in Figure 61. An electrodialysis cell is constructed like a bipolar filter-press electrolyzer, but only the two end chambers of the stack are fitted with electrodes. The compartments are sepa-

rated from each other alternately by cation (c) and anion (a) exchange membranes. The separation is based on the migration of ions in the electric field established by the cell voltage between the end electrodes. The material flux of a species i is $t_i j / z_i F$. The alternating cation and anion exchange membranes cause the contaminated electrolyte to be depleted, while the concentration, in this case of nickel and counterions, is enhanced in the concentrate. This separation is due to the fact that the transport numbers are close to unity for anions in the anion exchange membrane and for cations in the cation exchange membrane:

free electrolyte $t_i^+ \approx t_i^-$
cation membrane $t_i^+ \gg t^-{}_i$
anion membrane $t_i^+ \ll t_i^-$

Industrial applications have been reported, especially for nickel recovery [95], [96].

Electrodialysis does not result in the recovery of solid metals, but concentrates salt solutions. Although the concentration requirements for effluent treatment cannot be met, the concentration can be maintained on a level suitable for recirculation. Electrodialysis is generally not applicable to mixed electrolytes since suitable ion selective membranes are not available.

4.6.3. Anodic Treatment

By an electrochemical treatment of wastes either a partial (reduction of toxicity) or a complete decomposition of the pollutants can be achieved. In case of organic materials complete decomposition means the oxidation to carbon dioxide and as consequence a relatively high energy consumption for large organic molecules. The attempts for an electrochemical oxidizing treatment of wastewater or wastes can be classified into two categories:

Direct oxidation at the anode
Indirect oxidation using appropriate anodically formed oxidants (Cl_2, hypochlorite, peroxide, ozone, Fenton's reagent, peroxodisulfate)

A special case of indirect oxidation – frequently called *mediated electrochemical oxidation* (MEO) – is the use of metal ions with high oxidation potential (e.g., Ag(II), Co(III)) which can be electrochemically generated in a closed cycle largely avoiding emissions.

4.6.3.1. Direct Oxidation at the Anode

A suitable anode for direct oxidation has to meet mainly two requirements: high oxygen overpotential and corrosion stability.

A model described in [270] for the course of the anodic oxidation of an organic molecule assumes three major steps: (S indicates surface) Discharge of water forming an adsorbed hydroxyl species:

$$S[\ ] + H_2O = S[OH] + H^+ + e^-$$

The adsorbed OH is the "activated state" of water in oxygen-transfer reactions to the organic molecule R:

$$S[OH] + R = S[\ ] + RO + H^+ + e^-$$

Coevolution of O_2 by oxidation of water diminishing the current efficiency:

$$S[OH] + H_2O = S[\ ] + O_2 + 3\,H^+ + 3\,e^-$$

Phenol and its derivatives are the most frequently investigated molecules of electrochemical oxidation studies. Different anode materials such as platinum as reference electrode [271], nickel, glassy graphite, and titanium-supported oxide electrodes (IrO_2, RuO_2, PbO_2, and SnO_2 [272], [273]) and Bi as well as Fe-doped PbO_2 [270] were tested. A high oxidation rate was achieved with lead dioxide anodes using a packed-bed cell [274], [275]. The oxidation of phenol was complete at optimum conditions of pH and temperature in these experiments; the main product was carbon dioxide, benzoquinone and maleic acid were identified as byproducts.

The oxidation of numerous aromatic compounds has been investigated and for industrial wastewater treatment the use of a pilot plant equipped with Ti/SnO_2 anodes is reported [276].

Other applications that have been studied are direct anodic oxidation of sugars, alcohols, distillery effluents, dyes, aromatics, etc. [277].

For the direct oxidation of SO_2 in solution a kinetic study has been carried out using Pt, Pd, Ru, Ir, Rh, Re, and Au as anode materials [279]. The DSA PdO_x/Ti showed the highest electrocatalytic activity in these experiments

Figure 61. Nickel recovery from electroplating rinsing water by electrodialysis [267], [269]: a) Anion exchanger; c) Ccation exchanger

whilst $RuO_x - TiO_2/Ti$ and $IrO_x - TiO_2/Ti$ were inactive. A problem for the oxidation of SO_2 is to avoid the formation of elemental sulfur at the cathode.

The direct anodic oxidation of SO_2 as a method for flue gas treatment has been studied at several electrodes (see, e.g., [280]). At graphite electrodes sulfate and dithionate are formed as products. A continuous neutralization of the generated acid is required in the process. Numerous fundamental investigations and even bench scale experiments have been performed for the anodic treatment of aqueous effluents containing further inorganic pollutants, e.g., cyanide [281], thiocyanate [278], and sodium dithionite [282].

4.6.3.2. Indirect Oxidation

The most used oxidant electrochemically generated belonging to this category is chlorine or hypochlorite, ozone is the other prominent oxidant which can be produced electrochemically. In addition peroxide, Fenton's reagent [283], and peroxodisulfate are used occasionally. ABB Ltd. and OxyTech Ltd. use hollow, cylindrical fluorocarbon-impregnated carbon anodes for ozone generation in a solid-polymer electrolyte cell [277].

As already mentioned the use of redox couples with high oxidation potential such as Ag(II)/Ag(I) (1.98 V vs. NHE) and Co(III)/Co(II) (1.82 V vs. NHE) can completely oxidize organic compounds to CO_2. Therefore this *mediated indirect oxidation method* was developed for the treatment of hazardous organic wastes containing only a limited amount of water. The oxidant is continuously generated electrochemically in a closed cycle. The method was originally used in the nuclear industry to dissolve refractory plutonium dioxide in nitric acid [284], [285]. This experience initiated the treatment of mixed (radioactive) wastes (e. g., tributyl phosphate, solvent of the Purex Process) at the Savannah River Laboratory, USA and at AEA Dounreay, UK. The successful experiments launched process development activities at the Lawrence Livermore Laboratory [286], at AEA Dounreay [287], and at the Forschungszentrum Karlsruhe [288], and the method was ap-

plied to a plurality of hazardous wastes. The principle of this process is shown in Figure 62. Ag(II) is generated anodically from Ag(I) in an aqueous nitric acid solution using an electrochemical cell which is divided by a membrane. In the cathodic compartment nitric acid is reduced [289] to NO which can be regenerated to nitric acid by oxidative absorption in columns [290].

Figure 62. Principle of the MEO process

In this procedure, using two electrochemical cells, one for destruction of organics and the other for nitric acid recovery, hydrogen is the final cathodic reaction product. Investigations of Forschungszentrum Karlsruhe together with Eilenburger Elektrolyse- und Umwelttechnik have combined these two electrochemical cells into one, using silver containing nitric acid as anolyte and sulfuric acid as catholyte, thus avoiding NO formation at the cathode.

For the process development destruction experiments with different model substances and real wastes were performed both in a laboratory and in a bench-scale plant (Fig. 63). The experiments on a laboratory scale were caried out in a small filter press cell. Anode and cathode compartment were divided by a cation exchange (Nafion 450) membrane. Both electrode areas were 11 cm^2 and the volume of anode and cathode compartment was 6 cm^3 each [291]. The bench sale plant is designed similar to the laboratory plant with a scale up factor of 100. The central part of this plant consists of a monopolar electrochemical cell (ELECTROCELL AB, Sweden) or a bipolar cell from Eilenburger Elektrolyse- und Umwelttechnik GmbH (Germany). Both cells have anode and cathode areas of 0.12 m^2 each. A platinum foil anode is used, titanium or carbon serve as cathode. The maximum current density is limited by the Nafion 450 membrane to 5 kA/m^2 corresponding to a maximum current of 600 A. Liquid organic waste is fed into the anodic cycle by a pump, solid waste is fed into the anodic glass vessel from the top. Due to high flow rates of the electrolyte (up to 1500 L/h) the organic waste is finely dispersed in the electrolyte to minimize the transport inhibition at the aqueous – organic phase boundary layer [292].

Figure 63. Bench scale MEO plant at Forschungszentrum Karlsruhe

In case of degradation of chlorinated organic compounds intermediate precipitates of silver chloride occur which are redissolved in presence of an excess of Ag(II) by oxidation of chloride to perchlorate, which is enriched in the anolyte and can be separated from time to time as potassium perchlorate by cooling crystallization [293].

In the laboratory plant the destruction of a large variety of different, mostly chlorinated, model substances were investigated. In all experiments the electrolyte consisted of 0.5 M $AgNO_3$/7 M HNO_3. The experiments were carried out with current densities between 1 and 5 kA/m^2 and reaction temperatures of 40 – 90 °C. All selected model substances with the exception of hexachlorobenzene could be destroyed to more than 99 %. As reaction products always CO_2 and small amounts of CO were formed.

Moreover, several organic multicomponent waste mixtures from the chemical industry were treated in the laboratory and bench scale plants. The main components were benzoyl chloride, chlorobenzoyl chlorides, chlorobenzaldehyde, benzotrichloride, and benzoic anhydride. The

Figure 64. Mobile demonstration plant for destruction of chlorinated organic wastes

experiment was performed at 60 °C using a current density of 4 kA/m^2. At the start of the experiment CO_2 evolution occurred and current efficiencies up to 100 % were achieved. After 60 min CO_2 evolution decreased and O_2 formation, caused by water oxidation, increased.

Based on the described experiences and founded by the European Commission in the frame of a CRAFT project, a mobile demonstration plant was designed and built, which has been operated on an industrial site since March 1999 (Fig. 64). In case of destruction of chlorinated organic wastes, the plant offers both possibilities, separation of silver chloride from the anolyte and recovery of silver or oxidizing the organic chlorine to perchlorate and winning of potassium perchlorate. Sulfuric acid is used as catholyte, generating hydrogen at the cathode as a valuable byproduct. The migration of silver ions from the anolyte through the membrane into the catholyte was determined to be only 0.03 g $A^{-1}\,h^{-1}$. These silver ions are reduced and deposited at the cathode, flushed out periodically, separated from the catholyte and recycled to the anolyte.

4.7. Electrochemical Gas Purification

4.7.1. General Aspects

An increasing demand for off-gas purification, particularly for smaller scale power plants, heating combustion units, or chemical plants, has encouraged the development of new concepts of electrochemical gas purification techniques. Many gaseous pollutants, such as chlorine, hydrogen sulfide, nitrous oxides, or sulfur dioxide permit electrochemical conversion in an aqueous environment, since the standard potentials of the corresponding reactions are all within the stability range of aqueous electrolytes:

$$2\,Cl^- \rightleftharpoons Cl_2 + 2\,e^- \quad E^o = 1.360\,V$$
$$H_2S \rightleftharpoons S + 2\,H^+ + 2\,e^- \quad E^o = 0.142\,V$$
$$NO + 2\,H_2O \rightleftharpoons NO_3^- + 4\,H^+ + 3\,e^- \quad E^o = 0.957\,V$$
$$NO_2 + H_2O \rightleftharpoons NO_3^- + 2\,H^+ + 3\,e^- \quad E^o = 0.775\,V$$
$$SO_2 + 2\,H_2O \rightleftharpoons SO_4^{2-} + 4\,H^+ + 2\,e^- \quad E^o = 0.138\,V$$

Different concepts for electrochemical gas purification can be found in the literature [219]. In any case, the initial step is absorption of the pollutant species into a liquid phase. Since the solubility of several gases in aqueous solutions is too low, the transfer from the gas phase into the aqueous phase must be supported by a reaction, which converts the primarily dissolved species permanently to a more soluble one. In the simplest case, this can occur either by direct conversion at the electrode of an electrochemical cell [293, 294, 295], or indirectly via chemical reaction with a redox mediator, which can be electrochemically regenerated in a subsequent step. Homogeneous and heterogeneous catalysts have been applied as redox mediators. The advantage of heterogeneous mediators, such as oxides, is that a separation of the reaction products from

the mediator is not necessary. Both, the electrochemical conversion of the pollutant and the electrochemical regeneration of the redox mediator can be achieved either by an inner cell or an outer cell process, as illustrated in Figure 65 [297].

Figure 65. Electrochemical gas purification by inner cell and outer cell processes

Direct electrochemical conversion of gases by an inner cell process can be carried out in a specially designed electrochemical absorption column, which consists of a three-dimensional packed bed electrode of conducting particles in contact with a cylindrical feeder electrode and a counterelectrode separated by a porous diaphragm or ion exchanger membrane [293, 294, 295].

Figure 66 shows schematically the construction of such a device, which usually operates under countercurrent flow conditions of gas and liquid phases. The dissolved pollutant is directly converted at the surface of the packed bed electrode. Such a device exhibits high space – time yield and has been successfully tested for electrochemical absorption of sulfur dioxide and chlorine [295], [298], [299].

Indirect electrochemical processes with *homogeneous redox mediator* are the so-called "Peracidox"process developed by Lurgi [300] using peroxodisulfate, and the modified "Mark 13 A" process developed at the Joint European Research Center Ispra [301], using bromine as mediator as the redox mediator for indirect SO_2 oxidation. In both cases the electrochemical regeneration of the redox mediator is performed by an outer cell process in a separate electrochemical cell.

Processes with *heterogeneous redox mediators* are the lead dioxide catalyzed oxidation of SO_2, suggested by Strafelda [302] and the combined electrochemical and catalytic removal of SO_2 at a Cu_2O/Cu^{2+} catalyst [303]. Porous gas diffusion electrodes have been employed for the conversion of SO_2 using pyrolyzed Co phthalocyanines as electrocatalyst [304]. Electrode technology adopted from the fuel cell technology have also been used for effluent gas treatment. A cell construction similar to that of a molten carbonate fuel cell with porous electrodes and a molten $Na_2S - Li_2S$ electrolyte at 350 °C has been examined for removal of SO_2 and H_2S [305, 306, 307, 308]. High-temperature solid-state electrochemical cells based on Y_2O_3-stabilised ZrO_2(YSZ) and porous palladium electrodes have been studied for the successful electrochemical removal of both NO and CH_4 at 650 – 750 °C in an oxidizing atmosphere [309]. NO is reduced to N_2 and CH_4 is oxidized to CO_x.

4.7.2. New Process Developments

Since flue gases not only contain SO_2 but to a certain extent also NO_x, the development of processes for the simultaneous removal of both components has been the subject of recent investigations [299], [310, 311, 312, 313].

The cerium(IV)-assisted process [310], [311] is an indirect outer cell process with Ce^{4+} as homogeneous redox mediator for the simultaneous oxidation of SO_2 and NO_x to sulfuric acid and nitric acid. The acidic solution is continuously fed down to the anode compartment

Figure 66. Scheme of an electrochemical absorption column with three-dimensional particle bed electrode

of an electrochemical cell where Ce^{4+} is regenerated. When the solution has reached a critical concentration of approx. 30 – 40 % HNO_3 and H_2SO_4, separation of the nitrate effluent from the sulfate solution and recycling of Ce^{3+} are performed in a separate unit, where the nitric acid is first separated by distillation and the excess of sulfuric acid is then continuously removed by liquid – liquid extraction [314], [315].

The lead dioxide dithionite process [299], [312], [313] combines direct and indirect conversion of SO_2 and NO_x, respectively, in two steps with dithionite as homogeneous redox mediator for the indirect reduction of NO_x and lead dioxide as heterogeneous catalyst and mediator for the direct oxidation of SO_2. The gas mixture first enters an absorption column, where NO is absorbed by the complexing agent Fe(II)EDTA and simultaneously reduced with dithionite. Dithionite is continuously regenerated by cathodic reduction of SO_3^{2-} in an electrochemical cell. The second component, SO_2, passes the NO absorption column without reaction and enters an electrochemical cell, for example as shown in Fig. 66, where it is oxidized directly to sulfuric acid at the anode. A pilot plant for the treatment of 100 m^3/h (STP) of flue gas with 600 ppm NO inlet concentration had been tested on an industrial site (Brite Project 2026).

Microkinetic studies of NO_x absorption revealed that the degree of NO conversion can be significantly improved, if Fe(II)EDTA is present in the absorption solution at a low content. Another interesting aspect of electrochemical promotion of environmentally important heterogeneous gas phase reactions is the so called NEMCA effect (non-faradaic electrochemical modification of catalytic activity). NEMCA significantly increases the catalytic activity and selectivity of metal and metal oxide catalysts deposited on solid electrolytes such as YSZ or β"-Al_2O_3 by electrochemical polarization of the catalyst electrode [316, 317, 318]. Technical ap-

plications are still in the initial stage of development.

4.8. Electrochemical Shaping

Shaping pieces of metal by controlled anodic dissolution – controlled with respect to dissolution depth in three dimensions – is the essential aspect of electrochemical metal shaping [319, 320, 321]. This technique includes electropolishing, electrolytic or electrochemical grinding, and electrochemical machining. The last, electrochemical machining, is the fastest, most vigorous form of spatially controlled anodic metal dissolution.

Figure 67. Voltammogram of nickel, a passivating metal, in 9 M HCl [320]

Anodic corrosion, the fundamental phenomenon behind these three techniques, is characterized by the shape of the current – voltage curve in Figure 67. Anodic dissolution, which proceeds at a sizable rate in the subpassive voltage region, increases with anodic polarization. Its rate drops sharply, by several orders of magnitude, at the passivation potential, at which a dense semiconducting oxide hydrate film forms, and prevents further dissolution. At much higher potentials, however, this film breaks down, and vigorous transpassive dissolution of the metal is observed [319], [322]. If a compound of low solubility precipitates on the surface as a more or less porous deposit, instead of a passivating film, then anodic dissolution is inhibited, but the current density remains several orders of magnitudes higher than in the case of passivation. In such cases anodic dissolution usually is limited by mass transfer of the corrosion products through the pores of the deposited layer.

This mass tranfer-controlled dissolution through layers of precipitates is the principle governing electropolishing (Fig. 68A), whereas transpassive high current density corrosion is used for electrochemical machining and electrochemical grinding (Fig. 68B and C). Electrochemical grinding, which combines anodic dissolution with limited mechanical grinding is advantageous whenever a component of the alloy is not dissolved electrochemically but sticks to the surface and must be removed continuously along with the base metal. This is the case for cemented carbides as well as nitrides and borides of transition metals or refractory metals.

For processing superalloys and refractory metals, which came into use in the aerospace industry and for the construction of steam and gas turbines in the 1960s and early 1970s, the electrochemical methods – electrochemical machining, electrochemical grinding, and electrochemical polishing – are especially suitable. These methods, with the exception of electropolishing, are not likely to replace mechanical processing of conventional metals and alloys because the electrochemical techniques are expensive and too sophisticated to be used for softer alloys.

Electropolishing. Figure 67 shows the current – voltage curve for anodic dissolution of nickel in 9-N HCl solution with a limiting current density of the order of 100 mA/cm^2. This mass transfer-controlled dissolution rate is caused by formation of a relatively thin layer of porous oxide hydrate. The metal cations that are formed by anodic dissolution can leave the metal surface only by diffusion through pores. Since there is good reason to believe that the pores are randomly distributed and formed and closed at random, dissolution should also be random with no preference for particular crystal faces. Consequently, etch patterns are not observed.

The polishing effect is attributed to higher local dissolution rates of the elevated parts of the initially rough surface because of the lesser thickness of the porous oxide hydrates there. Table 17 lists the conditions and electrolyte compositions for electropolishing of metals. All the electrolytes contain components or establish a pH that causes the formation of only moderatey soluble oxide hydrates or salt deposits.

Figure 68. Schematic electrochemical shaping
A) Electrochemical polishing (– – – initial contour); B) Electrochemical machining; C) Electrochemical grinding

Such deposits form on the metal surface under steady-state conditions at current densities of ca. 300 – 3000 mA/cm^2.

Electrochemical Machining (ECM). For a practical electrochemical machining process, the metal must be removed at a cutting rate of 0.25 cm/min or more, corresponding to current densities > 160 A/cm^2. At these current densities, the electrolyte gap between the cathode and the workpiece must be adjusted continually to 0.005 – 0.13 cm to conserve electric energy. In addition, the anodically generated metal ions, hydroxides, and debris, the cathodically evolved hydrogen, and the dissipated Joule heat must be removed efficiently by vigorously pumping the electrolyte through the narrow gap between the cathode and workpiece. In order to keep ohmic voltage drop across the interelectrodic gap as low as possible, the electrolytes must have high conductivity.

Table 18. Electrolytes for electrochemical machining [320]

Metal	Electrolyte	Remarks
Aluminum and aluminum alloys	$NaNO_3$ (100 – 400 g/L)	excellent surface finish
Cobalt and cobalt alloys	$NaClO_3$ (100 – 600 g/L)	
Molybdenum	NaOH (40 – 100 g/L)	NaOH consumed and must be added continuously
Nickel and nickel alloys	$NaNO_3$ (100 – 400 g/L)	
	$NaClO_3$ (100 – 600 g/L)	good surface finish, good dimensional control, low metal removal rate
Titanium and titanium alloys	NaCl (180 g/L) + NaBr (60 g/L) + NaF (2.5 g/L)	good surface finish, good dimensional control, good machining rate
	$NaClO_3$ (100 – 600 g/L)	
Tungsten	NaOH (40 – 100 g/L)	NaOH is consumed and must be added continuously
Steel and iron alloys	$NaClO_3$ (100 – 600 g/L)	excellent dimensional control, brilliant surface finish, high metal removal rate, fire hazard when dry
	$NaClO_3$ (100 – 400 g/L) $NaNO_3$ (100 – 400 g/L)	

Commercial ECM machines apply a maximum voltage. This is distributed between the sum of the anodic and the cathodic overpoten-

Table 17. Electrolytes for electropolishing metals [320]

Metal	Electrolyte	Current density, mA/cm^2	Temperature, °C	Polishing time, min
Aluminum	20 wt % $HClO_4$ + 80 wt % acetic anhydride *	200 – 400	≤38	15
Copper	63 wt % H_3PO_4 + 37 wt % H_2O	20 – 50	22	5
	65 wt % H_3PO_4 + 15 wt % H_2SO_4 + 6 wt % CrO_3 + 14 wt % H_2O	200 – 250	22 – 25	2 – 5
Lead	30 vol % $HClO_4$ + 70 vol % glacial acetic acid *	1300 – 1600	22	5
Nickel	73 wt % H_2SO_4 + 27 wt % H_2O	1000 – 3000	22	2
	65 wt % H_3PO_4 + 15 wt % H_2SO_4 + 6 wt % CrO_3 + 14 wt % H_2O	200 – 250	22 – 25	2 – 5
Tin	20 vol % $HClO_4$ + 80 vol % acetic anhydride	600 – 1000	32	8 – 10
Tungsten	10 wt % $NaNO_3$ + 90 wt % H_2O	200 – 400	22	20 – 30
	Na_3PO_4 (160 g/L)	600	38 – 49	10
Zinc	25 wt % KOH + 75 wt % H_2O	1000	22	15
	17 wt % CrO_3 + 83 wt % H_2O	2000		
Brass	16 wt % CrO_3 + 84 wt % H_2O	2000		
	70 wt % H_3PO_4 + 30 wt % H_2O	500	26	5
Steel, carbon	48 wt % H_3PO_4 + 40 wt % H_2SO_4 + 12 wt % H_2O	3000	35 – 49	10
	10 wt % $HClO_4$ + 90 wt % glacial acetic acid	1500 – 2500	26	0.5 – 2
Steel, stainless	30 wt % H_3PO_4 + 60 wt % H_2SO_4 + 10 wt % H_2O	1800	49	2
	42 wt % H_3PO_4 + 45 wt % glycerol + 13 wt % H_2O	100 – 600	93 – 149	8 – 15

* Especially hazardous.

tials, which determines the current density and hence the dissolution rate, and the ohmic voltage drop across the interelectrodic gap. The ohmic voltage drop increases with gap width and current density. Therefore, for every cutting rate and voltage there is one gap width that is self-adjusting and that can be kept steady during the process, the so-called equilibrium gap.

Nevertheless, short circuits, which can severely damage the tool, must be avoided, and most ECM machines are protected against such damage by special sensing devices and ultrafast electronic switches.

Figure 69 shows how electrochemical machining works in the case of electrochemical drilling or sinking. The tool is a cylindrical cathode, the wall of which is covered with an electrically insulating coating. Current densities around 300 A/cm^2 flow between the bottom of the hole and the cathode, and a vigorous stream of electrolyte flushes the dissolved metal ions and solids out of the hole.

Immediately behind the cathode face there is a region where electropolishing takes place because of the reduced current densities. Consequently, electrochemical machining in most cases produces an excellent furnace finish.

Most important for successful electrochemical machining is the choice of the electrolyte. Its composition should allow metal dissolution with current densites up to several hundred amperes per square centimeter while preventing the precipitation of insoluble salts and oxides. Alkali-metal chlorates and perchlorates, which can be hazardous, have proved to be suitable ECM electrolytes. Table 18 lists the electrolyte and its concentration in typical ECM electrolytes.

Figure 69. Schematic electrochemical sinking machine [320]
a) Cathodic tool; b) Electrolyte inlet; c) Electrolyte outlet; d) Anodic workpiece; e) Insulating coating; f) Shield

Electrochemical machining became popular for processing high-strength metals and alloys and refractory metals. Some of the procedures for which ECM can be used are shown schematically in Figure 70. Die sinking is also possible. Sinking the cathode tool into the workpiece produces the cavity used for casting.

Figure 70. Sketches of various electrochemical machining operations [320]
A) External shaping; B) Cavity sinking; C) Plunge cutting; D) Turning; E) Trepanning; F) Internal grooving

In all these operations overcuts due to the action of stray currents cannot be avoided. Computed current-density distributions have always turned out to be insufficiently accurate to prevent the overcuts. Shaping is carried out by empirically changing the tool dimensions, current density, electrolyte concentration, electrolyte flow velocity, etc.

Electrochemical Grinding. Diamonds, α-alumina (corundum), or another hard material, the grinding powder, is embedded into the surface of a grinding wheel of copper or copper bronze, which serves as the cathode. The grinding powder is pressed into the metal surface and held in place by plating the studded surface with a layer of nickel. With an optimum load of 3.0 carats/cm^2, the grinding powder is exposed to a height of only 10 to 60 µm by etching the nickel away in an electropolishing bath.

The diamond (or corundum) grains do not serve themselves for grinding, but rather define and maintain the width of the electrolyte gap between the grinding wheel and the workpiece. Therefore, only light pressure is used to press the grinding wheel and the workpiece together. Around 90 % of the metal is removed by anodic dissolution. Fully hardened steels can be processed without difficulty and without detectable wear of the tools because nearly 100 % of the metal is removed by anodic dissolution. Current densities of 12 – 40 A/cm^2 approach those used for ECM; mixtures of chlorides and nitrates serve as electrolytes. Vigorous pumping and copious electrolyte exchange is vital for electrochemical grinding.

Unlike mechanical grinding, electrochemical grinding leaves no scratches, grooves, or tool registry marks. Current densities must not be too high if increased surface roughness is to be avoided.

5. Organic Electrochemistry

5.1. Introduction

Organic electrochemistry [323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354] provides a very versatile and powerful means for the

selective reagent-free reduction or oxidation of organic compounds. Organic substrates are activated by addition (reduction) or removal (oxidation) of electrons by a heterogeneous electron transfer reaction with the electrode. Starting from neutral compounds, either radical anions (reduction) or radical cations (oxidation) are formed (Fig. 71). Therefore, organic electrochemistry is regarded as the chemistry of radical ions. In contrast to the use of particular redox reagents, the selectivity of the electrochemical reaction can be determined by the selection of the electrode potential (see Section 5.2). Furthermore, as the electrons are mass-free, no waste from spent reagents is produced. The ecologically and economically problematic separation and treatment of waste materials can be avoided to a large extent.

Figure 71. Electrochemically accessible reactive intermediates

From the retro-synthetic point of view, electrochemical redox reactions provide easy pathways to accomplish the principle of redox-umpolung (polarity reversal). As can be seen in Figure 71, oxidation of an electron-rich neutral compound will lead to an electrophilic radical cation, or starting with a nucleophilic anion, anodic oxidation may lead to an electrophilic cation. In the mirror image reductions, an electron-poor neutral compound is transformed to a nucleophilic radical anion, or an electrophilic cation will end up as a nucleophilic anion.

Accordingly, organic electrochemistry is an inherently non-pollutant technology. Electrochemical activation of organic molecules supplements the conventional chemical or catalytic techniques, which involve thermal or photochemical activation.

Organic electrochemistry is a mature field of organic synthesis. A very broad variety of reactions can be performed in all areas of organic chemistry [323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354]. Although the electrochemical step usually is only one step in multi-step transformations, it is often the key-step generating an activated intermediate. The electrochemical reaction is mostly followed by other chemical steps leading to the product. Chemical side reactions must be suppressed by proper selection of the reaction conditions. Product separation from the solvent – electrolyte system is very often a limiting factor which has to be optimized by means of chemical engineering.

5.2. Perspectives of Electroorganic Reactions in Industry

Although, electroorganic syntheses are among the oldest reactions in organic chemistry, e.g., the Kolbe dimerization of carboxylic acids [355], and although the electrochemical methodology has quite attractive features for technical use (see Section 5.3), up to now their application in industry is still limited. Only the tetraethyllead formation (Nalco) [356], [357] which seems to be discontinued, and the cathodic hydrodimerization of acrylonitrile to give adiponitrile [357, 358, 359, 360, 361, 362], which is the largest commercial electroorganic process with a total output of about 300 000 t/a (30 % of the total world production of adiponitrile), have found industrial realization on the scale of commodity chemicals. In contrast, a considerable number of small and medium size processes are performed in industry especially in the fine chemicals area and more are expected to come. Because of secrecy requirements in industry there is a lack of exact data. Nevertheless, in the field of medium scale productions, especially the anodic formation of aromatic aldehydes by side-chain oxidation of alkyl aromatics developed by BASF [363], [364] and the production of perfluorinated organics performed by 3M and Phillips Petroleum [365], [366] are successful by industrial means and thereby are impressive examples. The understanding of the underlying mechanisms and the preparative potential of electroorganic techniques has furthered the interest in this methodology also in industrial laboratories. A good overview of the prepar-

ative potential is found in a number of excellent monographs and reviews [323,324,325,326,327,328,329,330,331,332,333,334,335,336,337,338,339,340,341,342,343,344,345,346,347,348,349,350,351,352,353,354]. The patent literature on organic electrosyntheses in industry up to 1986 has also been reviewed intensively [363].

Organic electrochemical transformations must compete with other chemical redox processes, i.e., mainly catalytic processes using hydrogen (reduction) or oxygen (oxidation) as reagents. Therefore, it is necessary to give an overview on the advantages and risks which are encountered when electrochemical reactions are to be implemented in industry. The advantages of electroorganic reactions may be summarized as follows:

1) The selectivity of the reaction can be influenced by the applied electrode potential which can be controlled by the current density. In contrast to the common redox reagents (potential range mostly between + 1 to − 1 V vs. SHE), the potential can be varied continuously and extended up to 2 V in both directions.
2) The selectivity can also be enhanced by careful selection of the reaction conditions at the phase boundary, e.g., by selection of the electrode material and the electrolyte composition.
3) The high selectivity of electroorganic reactions allows for the selective transformation of a certain functional group within a polyfunctional molecule. This is especially important for the synthesis of high-value specialty products.
4) The reaction rate can be controlled by the applied current density.
5) The turnover degree of the starting material can be fixed by the charge consumption.
6) The reaction conditions are very mild. Usually, electrolysis is performed at ambient temperature and pressure. The rate of the electron transfer is not strongly influenced by the temperature. Therefore, lowering the reaction temperature will not diminish the electron transfer rate but eventually lower the tendency for chemical side reactions.
7) The pollution of the environment by spent reagents can be avoided. The possibility of regenerating redox reagents electrochemically in situ (indirect electrolysis, see Section 5.3.1) allows the use of environmentally unfriendly systems such as manganese(III) or chromium(VI) in a closed loop. Thus, the product quality can be enhanced. The control of the reaction and its automation in terms of a continuous processing can be achieved easily by proper selection of the electrical parameters.

On the other hand, some problems have to be solved for a successful application of electroorganic processes in industry:

1) For electrochemical reactions, special reactors (electrolysis cells) are required. Fortunately, a large number of electrolysis cells are commercially available nowadays for almost all types of electrochemical processes ranging from production scale down to laboratory size (see Section 5.4.3).
2) In principle, electrochemical reactions are heterogeneous in nature. They take place at the electrode/electrolyte phase boundary. Therefore, for technical applications optimization of the space – time yield is particularly important. This can be achieved by using a high electrode surface-to-volume ratio by application of electrodes with very high specific surface area (see Section 5.4.2). In other cases, a mediator system which acts as an electron shuttle between electrode and substrate may accelerate the reaction rate and avoid electrode fouling by shifting the rate-determining redox reaction into the homogeneous solution (indirect electrolysis, see Section 5.3.1).
3) The relatively low conductivity of organic solvents makes the addition of a supporting electrolyte necessary. An exception can only be made when solid polymer electrolytes are used. The supporting electrolyte must dissociate in the solvent. At the end of the electrolysis, it must also be separated from the product which can cause problems and can be costly. This problem, however, can be diminished by using electrolysis cells with very small gaps between the electrodes (capillary gap cells) so that only very low concentrations of supporting electrolyte are needed (see Section 5.4.3). Typical solvents for performing electroorganic processes at indus-

trial scale are mainly alcohols (especially methanol), acetic acid, or dimethyl formamide. However, the most important solvent for industrial use is water. Very often, co-solvents such as alcohols or acetonitrile are used to increase the solubility of the organic substrate. Aqueous sulfuric acid is also a traditional electrolyte. However, the acid has to be neutralized during work-up leading to the problem of waste salts. Emulsions or two-phase systems of water and an organic solvent are often more effective.

More than 200 electroorganic processes may have reached the pilot plant stage. The number and scale of processes which are really commercialized is lower and exceeds probably 100. The exact number cannot be determined because of commercial secrecy of industry [367]. The more detailed data given in [368,369,370,371,372] are also influenced by this lack of knowledge and should therefore only be used with care. Companies and research centers which are strongly involved in the development and application of electroorganic processes are:

- BASF in Germany as the leading company in the application of electrochemical processes including the manufacturing of adiponitrile, the formation of a variety of substituted benzaldehydes by side-chain oxidation of alkyl-substituted aromatics, the preparation of succinic dialdehyde and the application of electrodialysis.
- Hoechst in Germany has developed a number of bench scale and pilot plant scale processes. The epoxidation of hexafluoropropene was commercialized. For 90 years the company has been running the electrochemical regeneration of chromic acid on a large technical scale for the bleaching of montan waxes [373]. After take-over by Clariant 11 000 t/a of bleached montan waxes are produced at the plant in Gersthofen. A membrane process using dimensionally stable titanium anodes with lead dioxide coatings has been developed for this purpose and tested in pilot plants [374]. After restructuring of Hoechst, research in electroorganic chemistry seems to have been discontinued or taken over by Clariant.
- Hydro Quebec in Canada has developed a number of electrooxidations mainly using cerium(IV) as electrogenerated oxidizing agent. The manufacturing of anthraquinone via naphthoquinone seems to go in production at a cooperating company. Side-chain oxidations of alkyl aromatics seem to be also close to commercialization.
- Electricité de France (EDF) mostly in cooperation with Société Nationale des Poudres et Explosifs (SNPE) is very active in the development of electroorganic processes like the reductive carboxylation of benzylic halides to form the anti-inflammatory arylpropionic acids.
- Otsuka Chemical Co. in Japan is producing maltol (3-hydroxy-2-methyl-4-pyrone) by an electrochemical process and is very active in the study of a large number of other electrochemical processes.
- Asahi Chemical Co. in Japan is a producer of adiponitrile using the old Monsanto process in divided cells. It is also a manufacturer of dialkyl sebacate by Kolbe electrolysis of dialkyl adipate.
- Monsanto in the USA had been very active in the field of electroorganic synthesis. After restructuring the company, the research in this area was practically discontinued. The modern adiponitrile synthesis facilities in Great Britain have been sold to BASF and the production unit in the USA is now run by Monsanto's spin-off company Solutia Inc.
- Electrosynthesis Co. in East Amherst, New York, is very active in research, development and consulting in the area of industrial application of organic electrochemistry. Similarly, in India the Central Electrochemical Research Institute (CECRI) in Karaikudi and in Great Britain the Capenhurst Electricity Council Research Center (ECRC) are active research centers.

Other active companies are mentioned in Tables 20, 21, 22, 23, 24, 25, 26, 27.

5.3. Syntheses

5.3.1. Direct vs. Indirect or Mediated Electrochemical Reactions

In *direct electrochemical reactions* the substrate undergoes a heterogeneous redox reaction at the

electrode surface within the Helmholtz layer. The thus formed reactive intermediate, i.e., a radical ion, undergoes the chemical follow-up reaction to the product in the reaction layer. The steep concentration gradients near the electrode are one important factor in the chemical follow-up reaction of the electrogenerated intermediates. Second-order reactions of the intermediates can thus be obtained at high current densities.

In *indirect electrochemical reactions* [375, 376, 377], the heterogeneous reaction between the substrate and the electrode is replaced by a homogeneous redox reaction in solution between the substrate and an electrochemically activated and regenerated redox catalyst (Fig. 72). First-order reactions of the electrogenerated intermediates may be favored under these conditions. In addition, overpotentials for the reaction of the substrate at the electrode may be avoided and reactions may be accelerated. If electrode passivation causes problems for direct electrolyses, an indirect pathway could be an alternative because the electrode reaction of the substrate can thus be avoided. In many other cases, the selectivity properties of the redox catalysts can be used profitably in indirect processes. On the other hand, direct electrochemical reactions are less complicated because no additional catalysts must be added and separated.

Two types of redox catalysts are used in indirect electrolyses: (A) pure, outer-sphere or non-bonded electron transfer agents, and (B) redox reagents which undergo a homogeneous chemical reaction which is intimately combined with a redox step. This may be called inner-sphere electron transfer or bonded electron transfer mechanism.

Figure 72. Schematic representation of an indirect electrochemical process in the in-cell mode, given for an oxidation Med_{ox}, Med_{red} = Oxidized and reduced form of the redox catalyst = (mediator); SX_{ox}, SX_{red} = Oxidized and reduced form of the substrate; ET = electron transfer

In case (A), the mediator catalyzes the electron exchange between the electrode and the substrate. As compared with direct electrolyses, overvoltages may be reduced and passivation of electrode surfaces may be avoided. If the homogeneous electron transfer equilibrium is followed by a fast and irreversible chemical step, mediators can be used with redox potentials which are up to 500 mV lower than the standard potential of the substrate (electron transfer against the standard potential gradient). Also, slow heterogeneous electron transfers at the electrode surface can be replaced by fast homogeneous electron transfers in solution. This is especially valuable, if large biomolecules are the substrates. Typical examples of such electron transfer mediators are stable radical anions or dianions of mostly aromatic or heteroaromatic systems or the stable radical cations of substituted triarylamines [378], [379].

Table 19. Advantages and disadvantages of indirect (mediated) electrochemical reactions with regard to the type of electron transfer

Mechanism	Advantages	Disadvantages
A) outer-sphere pure ET	no overpotential no passivation electron transfer against the potential gradient is possible (up to ca. 500 mV) increase of the reaction rate by replacement of a slow heterogeneous ET step by a fast homogeneous one	selectivity is only determined by the potential difference between the mediator and the substrate and the rate of the follow-up reaction
B) inner-sphere	very large potential differences can be overcome (up to 2 V) selectivity is controlled by the chemical step which is accompanied with the ET	regeneration is often difficult because an additional chemical reaction is necessary to transform the reacted mediator into a form from which the active catalyst can be regenerated

In case (B), the homogeneous redox reaction of the electrogenerated and regenerated redox catalyst consists of a chemical reaction. For oxidations, these reactions may be hydride ion or hydrogen atom abstraction, oxygen transfer, or an intermediate complex or bond formation. For reductions, hydride or carbanion transfer from a metal complex is often observed. In all these cases, very large potential differences between the standard potential of the substrate and the redox catalyst may be overcome. The selectivity can be very high and may be tuned by the proper selection of the metal ions and the ligands in the case of metal complexes as redox catalysts. All chemical steps involved must be very fast for an efficient redox catalytic system. Most of the inorganic redox catalysts, especially transition metal complexes, are acting in this way. For oxidations, not only transition metal salts or complexes but also halide ions are applied. The advantages and disadvantages of mediated electrochemical reactions are summarized in Table 19.

If the electrochemical generation and regeneration of the redox catalyst and the homogeneous redox reaction with the substrate take place in separate reactors, this is called an *ex-cell process*. If both steps are performed in-situ in the same reactor, this is called an *in-cell process*. While the in-cell process requires a lower investment, the ex-cell process is easier to optimize because both steps, the electrochemical one and the chemical one, can be treated separately.

Typical examples of inorganic redox couples which are used for indirect electrolyses are

for oxidations:
Ce(III)/Ce(IV); Cr(III)/Cr(VI); Mn(II)/Mn(III); Mn(II)/Mn(IV); $Ni(OH)_2$/NiOOH; I^-/I_2; Br^-/Br_2; Cl^-/ClO^-;
for reductions:
Sn(IV)/Sn(II); Cr(III)/Cr(II); Ti(IV)/Ti(III); Zn(II)/Zn; Na(I)/NaHg.

5.3.2. Technically Important Processes Ordered by Reaction Classes

Technically important processes which have been developed in industry to the pilot plant stage (P) or have been commercialized (C) are presented in the order of reaction classes. Bench scale processes (B) are only reported in a few cases. As mentioned before, the status of the processes is not always exactly known to the public.

5.3.2.1. Electrochemical Substitution

Substitution at the Anode.

$$R\text{–}E + Nu^- \rightarrow R\text{–}Nu + E^+ + 2e^-$$

Principle: Substitution of an electrophile (E), mostly a proton or in rare cases a trialkylsilyl group by a nucleophile (Nu), mostly from the solvent such as alcohol, water, or acetic acid, or by a halide ion.

Anodic substitution reactions are useful for nuclear or side-chain aromatic substitutions or for substitutions in the α-position to heteroatoms like nitrogen, oxygen, or sulfur.

Several industrial processes make use of anodic side-chain substitutions of alkyl aromatics. Thus, aromatic aldehyde acetals are generated mostly at graphite anodes in the presence of methanol in a direct electrochemical process in

undivided bipolar capillary gap cells (see Table 20, examples no. 1 – 3). This process is commercialized and used intensively by BASF in scales of several thousand tons per year.

Other companies use indirect electrochemical processes applying electrogenerated manganese(III) (Table 20, no. 4) [380,381,382,383] or cerium(IV) (Table 20, no. 5) [384,385,386,387,388,389,390,391] as chemical oxidants in an ex-cell mode. The better solubility of cerium(IV) in aqueous methanesulfonic acid is advantageous as compared to the less soluble cerium ammonium nitrate (CAN), used for conventional oxidations. Based on developments by W. R. Grace, Hydro Quebec is currently intensively involved in the commercialization of nuclear and side chain substitutions of aromatic compounds using the system Ce(IV)/methanesulfonic acid.

Industrially important anodic aromatic substitution reactions are listed in Table 21. The formation of anthraquinone using electrogenerated dichromate in an ex-cell process has been developed in the UK (Table 21, no. 11). The electrochemical process is carried out in a filterpress type plate and frame membrane cell [377]. Hydro Quebec has developed a process for the nuclear (Table 21, no. 11 – 13) and side-chain oxidation of aromatics using electrogenerated Ce(IV) in aqueous methanesulfonic acid in an undivided bipolar plate and frame cell [384,385,386,387,388,389,390,391], [397], [398]. It is expected that a plant with a capacity of several thousand t/a will be constructed for the production of anthraquinone from electrogenerated naphthoquinone by reaction with butadiene.

The formation of hydroquinone from benzene via benzoquinone has been studied intensively (Table 21, no. 14). However, the process could not yet compete with the established methods and has therefore not been commercialized.

Perfluorination of hydrocarbons can only be achieved electrochemically in HF solution at nickel electrodes. A typical example for this technically extremely important process (Simons process developed by 3M Co.) is given below in Table 22, no. 17.

Partial fluorination can be obtained by the Phillips Petroleum process as indicated in Table 22, no. 18). Also a number of Japanese companies seem to perform electrochemical fluorinations on a commercial basis (Central Glass, Co.; Toyo Tannso Ind. Co.; Tokem Co.).

In a different way, perfluorinated functionalized compounds can be synthesized using electrogenerated peroxodisulfuryldifluoride which starts an in-situ additive telomerization with tetrafluoroethylene (Table 22, no. 19).

Selective monofluorinations especially in the α-position of heteroatoms or in benzylic positions by anodic oxidation in acetonitrile in the presence of $Et_3N \cdot nHF$ are promising for industrial application [410].

Anodic substitution can also occur easily in the α-position to heteroatoms like nitrogen or oxygen. Especially the α-methoxylation or acetoxylation of amides like *N*-acyl and *N*-alkoxycarbonyl derivatives of amines or amino acid derivatives leads to the synthetically very useful *N,O*-acetals which are powerful amidoalkylation reagents [411,412,413,414]. No practically useful chemical alternative exists. The formation of 2-methoxy-*N*-formylpiperidine from *N*-formylpiperidine has been reported to be developed to the pilot plant stage in Europe [369]. The *N,O*-acetals are starting materials for the synthesis of complex organic molecules like alkaloids. By elimination of methanol an alternative pathway to *N*-vinyl amides is opened [415].

Table 20. Industrially important anodic substitution reactions: aromatic side chain substitutions

No.	Substrate	Product	Status	Conditions	Remarks and references
1	4-Methoxytoluene	4-methoxybenzaldehyde dimethyl acetal	C (BASF)	direct electrolysis; MeOH/KF or other supporting electrolyte; undivided capillary gap disk-stack cell	[363], [364] several thousand t/a
2	4-*tert*-Butyltoluene	4-*tert*-butylbenzaldehyde dimethyl acetal	C (BASF)	direct electrolysis; MeOH/KF or other supporting electrolyte; undivided capillary gap disc-stack cell	[363], [364]
3	4-*tert*-Butyloxytoluene	4-*tert*-butyloxybenzaldehyde dimethyl acetal	C (BASF)	direct electrolysis; MeOH/KF or other supporting electrolyte undivided capillary gap disc-stack cell	[363], [367]
4	4-*tert*-Butyltoluene	4-*tert*-butylbenzaldehyde	C (ETH Zürich, Givaudan-Roure)	indirect electrochemical ex-cell process via electrogenerated Mn^{3+}; undivided bipolar plate and frame cell	[380,381,382,383]
5	Div. substituted toluenes	div. substituted benzaldehydes	P/C (Hydro Quebec)	indirect electrochemical ex-cell process via electrogenerated Ce^{4+} in aq. methane sulfonic acid; undivided bipolar plate and frame cell	[384,385,386,387,388,389,390,391] originally developed by W.R. Grace & Co.; commercial processes for anisaldehyde considered
6	*p*-Xylene	tolualdehyde	P/C (India)		
7	3,4,5-Trimethoxytoluene or 3,5-dimethoxy-4-hydroxytoluene	3,4,5-trimethoxybenzaldehyde by solvolysis of the intermediate quinone methide followed by air oxidation of the benzylic alcohol	C (Otsuka)	direct electrochemical oxidation in MeOH/NaOH	[392,393,394]
8	2-Methylpyridine (4-methylpyridine)	picolinic acid (isonicotinic acid)	C (Reilly Industry)	PbO_2 anode, aq. H_2SO_4, divided cell	[395] may be discontinued
9	4-Nitrotoluene	4-nitrobenzoic acid	C (India)	indirect electrochemical process via electrogenerated Cr^{6+}	
10	Nitrotoluenes	aminobenzoic acids	B/P (EDF)	paired indirect electrosynthesis using anodically generated Cr(VI) for the side chain oxidation and cathodically generated Ti(III) for the nitro group reduction (divided cell)	[396]

Table 21. Industrially important anodic substitution reactions: aromatic nuclear substitutions

No.	Substrate	Product	Status	Conditions	Remarks and references
11	Anthracene	anthraquinone			
			1) C (ECRC; L. B. Holliday with Cr^{6+}) 2) C (Hydro Quebec with Ce^{4+})	1) indirect electrochemical ex-cell process via electrogenerated Cr^{6+} in a divided parallel plate cell 2) via electrogenerated Ce^{4+} in methane sulfonic acid in an undivided bipolar plate and frame cell	1) [346], [377] 2) [384,385,386,387,388,389,390,391], [397]
12	Naphthalene	naphthoquinone	P/C (Hydro Quebec)	indirect electrochemical ex-cell process via electrogenerated Ce^{4+} in methanesulfonic acid in an undivided bipolar plate and frame cell	[384,385,386,387,388,389,390,391], [397] commercialization expected
13	1-Nitronaphthalene	5-nitronaphthoquinone	P (Hydro Quebec)	indirect electrochemical ex-cell process via electrogenerated Ce^{4+} in methanesulfonic acid in an undivided bipolar plate and frame cell	[398] formation of 1-aminoanthraquinone after reaction with butadiene and nitro group reduction
14	Benzene	benzoquinone	P	PbO_2 anode, aq. H_2SO_4, divided cell	[399,400,401,402] formation of hydroquinone possible by cathodic reduction in a paired electrosynthesis

No.	Substrate	Product	Status	Conditions	Remarks and references
17	Alkanoyl chlorides and fluorides; alkanoic sulfuric acid chlorides	perfluorinated alkanoic acid fluorides and sulfuric acid fluorides	C (3M, Bayer)	Simons process; Ni anode in liqu. HF	[365], [366], [406], [407]
18	Alkanes, chloroalkanes, carboxylic acids	partially fluorinated alkanes, chloroalkanes and alkanoic acid fluorides	P (Phillips Petroleum)	porous carbon electrodes; KF-2HF melt	[366]
19	Fluorosulfuric acid	peroxodisulfuryl difluoride	P (Hoechst)	undivided tank cell; glassy carbon anode, steel cathode; in fluorosulfonic acid/0.1 M alkali fluorosulfonate	[409] electrotelomerization of tetrafluoroethylene by electrogenerated peroxodisulfuryl difluoride

A phosgene-free synthesis of alkylisocyanates makes use of the indirect electrochemical oxidation in the α-position to nitrogen of formamides. Bromide in methanol solution acts as the redox catalyst which, presumably, is oxidized to the methyl hypobromite [416].

A different phosgene-free synthesis of isocyanates or carbamates starting from oxamates has been developed by Shell via substitution of a carboxylic function in the α-position to nitrogen by decarboxylative methoxylation (Non-Kolbe reaction) [417].

α-Hydroxylation of ketones can be performed anodically using iodide as a mediator in methanol solution leading to α-hydroxy acetals. These offer an industrially interesting way to acyloins [418]. Recently, BASF has commercialized the production of acetoin and adipoin according to this procedure [419].

Substitution at the Cathode.

$$R{-}X + E^+ + 2e^- \rightarrow R{-}E + X^-$$

Principle: Substitution of a nucleophile (X^-), mostly halogen, by an electrophile (E^+), mostly an alkyl group from alkyl halides, carbon dioxide, a carbonyl compound, a Michael acceptor or a silyl group from silyl halides.

Cathodic substitutive carboxylation starting from benzylic halides using carbon dioxide as electrophile has been developed industrially for the synthesis of the anti-inflammatory arylpropionic acids naproxen, fenoprofen, and ibuprofen.

In France, SNPE in cooperation with EDF has developed this process to the pilot plant stage using a sacrificial magnesium anode (see Section 5.4.2.2) in a so-called pencil-sharpener cell (see Section 5.4.3.2; Fig. 80) [420, 421, 422, 423]. Alternatively, these products can also be obtained by reductive carboxylation of acetyl-substituted aromatics (see below).

5.3.2.2. Electrochemical Addition

Addition at the Anode.

$$R{-}CH{=}CH{-}Y + 2\,Nu^- \rightarrow Nu{-}CRH{-}CHY{-}Nu + 2e^-$$

Principle: Addition of two nucleophiles (Nu^-), mostly from the solvent to an electron-rich double-bond.

Anodic addition reactions have been developed on a technical scale for the dimethoxylation of furan and furan derivatives using bromide as redox catalyst to give 2,5-dimethoxy-2,5-dihydrofurans as synthetic intermediates. This process is commercialized by BASF for the formation of succinic dialdehyde and by Otsuka, Japan, for the synthesis of maltol and ethyl maltol (Table 23, no. 1,2).

The epoxidation of double bonds has also been studied intensively in case of the bromide or chloride mediated formation of propylene oxide from propene via the intermediate formation

of BrO^- or ClO^- at the anode and of hydroxide at the cathode (Table 23, no. 3). Due to the formation of small amounts of halogenated byproducts and a limited space-time yield because of the low solubility of propene in the medium, this process never became commercialized. The synthesis of hexafluoropropylene oxide, however, has been carried out on a small scale by Hoechst (Table 23, no. 4). An electrochemical variant of the asymmetric bishydroxylation introduced by Sharpless has been developed by Engelhard Ltd. and ChiRex Ltd. in the UK, using a double mediator system consisting of ferricyanide and osmium tetroxide in the presence of chiral ligands (Table 23, no. 6) [433,434,435,436,437]. As an alternative to ferricyanide, electrogenerated iodine may be used [435], [436]. The double mediator system of Os(VIII)/ferricyanide without the use of the chiral ligands was already described in the late 1960s [437].

Addition at the Cathode.

$$-C{=}X + 2\,E^+ + 2e^- \rightarrow E{-}C{-}X{-}E$$

Principle: Addition of two electrophiles (E^+) to an electron-poor C-C-double-bond (C=C) or a C-heteroatom double-bond (C=X with X=N or O). Protons are mostly acting as electrophiles but also carbonyl compounds, carbon dioxide or alkyl and silyl halides are employed. Industrially important cathodic addition reactions are summarized in Table 24.

The electrochemical hydrogenation of double bonds can either be performed electrocatalytically at Raney nickel, palladium, or platinum modified electrodes [443], via electron transfer under Birch conditions to give the intermediate radical anion [444], or by direct electron transfer commonly using lead cathodes in sulfuric acid as electrolyte.

Other typical examples for the addition of protons are the reductions of carbonyl compounds such as aldehydes, ketones, or carboxylic acids and their derivatives to the corresponding alcohols or aldehydes (Table 25).

Cathodic hydrogenation reactions to form amines can be usefully applied to C=N double bonds like in imines and oximes or proceed via electroreductive amination of carbonyl compounds.

A novel synthesis of enantiomerically pure (*S*)-naproxene, an anti-inflammatory drug, has been developed by Searle and Solutia Inc. (Monsanto group). The first step is the cathodic addition of carbon dioxide as electrophile to an arylketone.

The formed α-hydroxy acid is subsequently dehydrated and the double bond homogeneously hydrogenated using chiral catalysts. The electrolysis takes place in an undivided cell using a lead cathode, a sacrificial aluminum anode and a tetraalkylammonium halide in DMF as electrolyte [464,465,466,467].

Table 23. Industrially important anodic addition reactions

No.	Substrate	Product	Status	Conditions	Remarks and references
1	Furan	2,5-dimethoxy-2,5-dihydrofuran	C (BASF)	indirect electrochemical in-cell process via the bromide/bromine couple in MeOH/NaBr in an undivided capillary gap disc-stack cell	[403]
2	Furfuryl-1-ethanol (also furfuryl-1-propanol)	2,5-dimethoxy-2,5-dihydrofurfuryl-1-ethanol and 1-propanol	C (Otsuka Chem. Co.)	indirect electrochemical in-cell process via the bromide/bromine couple in MeOH/NaBr	[424] part of the maltol and ethyl maltol synthesis
3	Propene	propylene oxide	P (Bayer, BASF, Olin, Dow, Univ. Dortmund)	indirect electrochemical in-cell process via the Cl^-/OCl^- or Br^-/BrO^- couple in H_2O/NaCl or H_2O/NaBr	[425] water reduction at the cathode to form hydroxide ions maintains the necessary pH value
4	Hexafluoropropene	hexafluoropropene oxide	C (Hoechst)	PbO_2 anode, divided cell, Nafion membrane, H_2O/HOAc/HNO_3	[426,427,428] status not known
5	Acetic acid and 1,3-butadiene	sorbic acid via γ-vinyl-γ-butyrolactone	B/P (Monsanto; Asahi Chem.)	indirect electrochemical process via electrogenerated $Mn(OAc)_3$	[429,430,431] addition of a carboxymethyl radical to 1,3-butadiene
6	Prochiral olefins	chiral 1,2-diols	P (Engelhard, ChiRex)	indirect electrolysis; ferricyanide/osmium tetroxide double mediator system in the presence of chiral ligands	[433,434,435,436,437] ferricyanide may be replaced by iodine electrogenerated from iodide

8	Glucose or mannose	sorbitol or mannitol	C (India, USA)	Pb cathode in acidic medium	[445], [446] probably discontinued; can be paired with the anodic formation of gluconate [447]
9	Oxalic acid	glycoxylic acid	P/C (Rhône-Poulenc; Steetley Chem.)	direct process; Pb cathode in H_2SO_4	[448,449,450] may also be paired with the oxidation of glyoxal to glyoxylic acid [451]
10	Anthranilic acid	*o*-aminobenzyl alcohol	P/C (BASF)	direct process; Pb cathode in acidic medium; divided membrane cell	[452]
11	2-Hydroxybenzoic acid (salicylic acid)	2-hydroxybenzaldehyde (salicyl aldehyde)	C (India)	Pb cathode in acidic medium	[453,454,455] process discontinued
12	3-Hydroxybenzoic acid	3-hydroxybenzyl alcohol	C (Mitsui Toatsu Chem. Co.)	Pb cathode in $H_2O/MeOH/H_2SO_4$; divided cell	[456] precursor for the synthesis of ethofenprox
13	Dimethyl terephthalate	4-hydroxymethyl benzoic acid methyl ester	P (Hoechst)	Pb or Hg cathode in MeOH/NaOAc	[457], [458]
14	1) Ammonium phthalamate from phthalic anhydride 2) Dimethyl phthalate	phthalide	B/P (BASF)	1) Pb cathode; pH 7 – 9 2) undivided capillary gap disk-stack cell with carbon electrodes in methanol/DMF	1) [459,460,461] 2) [462] *N*-methoxy-*N*-methylformamide is formed anodically as a couple product
15	4-Methylimidazole-5-carboxylic acid	4-methyl-5-hydroxymethylimidazole	P (Smith, Kline & French)	Pb or Hg cathode in H_2O/H_2SO_4	[463]

5.3.2.3. Electrochemical Transformations of Functional Groups

Functional Group Transformations at the Anode. Functional group transformations carried out technically include oxidations of alcohols and aldehydes to the corresponding carboxylic acids (Table 26). For montan wax bleaching, the crude montan wax, consisting mainly of esters of long chain alcohols and long chain acids is hydrolyzed under the acidic reaction conditions and the alcohol components are oxidized to the corresponding carboxylic acids by electrogenerated and regenerated Cr(VI). This is one of the most important electroorganic processes (see Section 5.2).

The indirect electrochemical oxidation of the aldehyde groups in aldoses to the corresponding aldonic acids (Table 26, no. 1) has been carried out industrially since 1930 and is still used today by Sandoz (Novartis) and in India. The bromide/hypobromite couple is used as the redox catalyst.

Functional Group Transformations at the Cathode. Cathodic functional group transformations are the reduction of cyano, nitro or amide functions to amino and aminomethyl groups. Reductive transformations of carbonyl compounds are treated as addition reactions of protons (see Section 5.3.2.2).

The cathodic reduction of aromatic nitro compounds to aniline derivatives is possible. Generally lead cathodes in acidic media are used. However, this process can usually not compete with the catalytic pathway [453], [475]. In developing countries the electrochemical method may be advantageous under special conditions. Thus, a considerable number of such processes are commercialized in India [368]. Sometimes, the processes are performed as indirect reactions using electrogenerated Ti(III) as the redox catalyst to lower the reduction potential and thereby decreasing the energy consumption [476]. The electrochemical methodology is technically more important for partial reduction of nitro groups to the hydroxylamine function in

buffered media ($HOAc/NH_4OAc/H_2O/EtOH$) [477] or for the reductive rearrangement to give *p*-aminophenol derivatives. Starting from nitrobenzene, *p*-aminophenol can be generated at copper or Monel cathodes in aqueous sulfuric acid at elevated temperature via the intermediate hydroxyl amine which rearranges under the reaction conditions (Bamberger rearrangement). If the cathodic reduction is carried out in the presence of alkanols, the corresponding alkoxy substituted anilines (*p*-aminophenol ethers) can be obtained. This reaction is unprecedented by other methods [478], [479]. Many companies have studied it including Bayer, Miles Laboratories (now Bayer), L. B. Holliday, PPG, and BASF. In India, the *p*-aminophenol formation seems to be carried out on a commercial scale [442].

Cathodic reduction of 3-nitropyridines in hydrochloric acid using a membrane-divided flow-cell leads to 3-amino-2-chloropyridines also via a Bamberger rearrangement. Thus, the formation of 3,4-diamino-2-chloropyridine from 4-amino-3-nitropyridine has been developed on the miniplant scale by Merck, Darmstadt [480].

Cyano groups can be electrochemically reduced to give aminomethyl functions. This reaction has mainly being applied technically for the reduction of cyanopyridines to give the aminomethylpyridines using lead cathodes in acidic media in a divided membrane cell. This process was commercialized by Reilly Tar but seems to be discontinued [346], [395], [481].

Electrochemical carboxamide reductions have been applied in the formation of isoindoles from phthalinides by Ciba-Geigy.

5.3.2.4. Electrochemical Cleavage and Elimination

Cleavage at the Anode. Cleavage reactions at the anode are until now in most cases of little interest for technical applications. They are mostly used for the cleavage of protecting groups. Oxidation in the α-position of heteroatoms can lead to the cleavage of carbon – oxygen, carbon – sulfur, carbon – nitrogen, and carbon – silicon bonds [482,483,484,485,486,487,488,489,490]. By cleavage of the carbon-nitrogen bond in amines, the formation of metabolites is possible because the anodic oxidation of nitrogen compounds equals the microsomal oxidation to a large extent [488]. This method has been applied to gain easy access to metabolites of pharmacological compounds to be studied toxicologically.

The anodic C–C bond cleavage of the 1,2-diol structures in starch to give dialdehyde starch has been studied intensively by the industry and has been performed technically via an indirect electrochemical process involving formation of electrogenerated IO_4^- at lead dioxide anodes. This reaction has been studied by Miles Laboratories (now Bayer) and is used commercially in India [442], [491], [492].

Starting from D-gluconic acid, decarboxylative cleavage of the C_1-C_2 bond leads to the formation of D-arabinose (Non-Kolbe electrolysis). D-glucose can also be used directly as the starting material [493].

Cleavage at the Cathode.

$$R\text{–}X + e^- \rightarrow R\text{–}X^{\cdot -} \rightarrow R^{\cdot} + X^-$$
$$R^{\cdot} + e^- \rightarrow R^-$$

In the cathodic cleavage, halogen, phosphonium, ammonium, nitrile, thioalkyl, or sulfonate groups can act as leaving groups and are replaced by hydrogen. A special case is the cleavage of the disulfide bond to form thiols. Selectivity between different leaving groups can be obtained by potentiostatic reduction. The application to deprotection has been used successfully [494], [495]. The selectivity in the cathodic cleavage of phosphonium salts has been used very early for the formation of optically active phosphine and phosphonium ions [496].

Industrially, besides the cleavage of carbon – halogen bonds (see Table 27) the cathodic cleavage of the disulfide group in cystine or cystine derivatives to give the corresponding cysteine or its derivatives has been studied and applied commercially (e.g., by Isochem, Nippon Chem., Degussa, Diamalt, Tanabe, Takeda, Ajinomoto, Electrosynthesis Co., Universidad de Alicante). The cleavage usually either takes place at lead cathodes in acidic media using a divided membrane cell or at carbon felt cathodes and a DSA anode with an aqueous ammonium hydroxide catholyte and a 3 M aqueous sulfuric acid anolyte [497,498,499,500,501,502,503,504]. If the cleavage of cystine is performed in the presence of chloroacetic acid in basic medium, *S*-carboxymethyl-L-cysteine can be obtained [503].

3-Exomethylene-cephem derivatives have been generated via reductive cleavage of the carbon – halogen or carbon – acetoxy function (Table 27, nos. 3, 4) [509,510,511].

Table 27. Industrially important cathodic dehalogenations

No.	Substrate	Product	Status	Conditions	Remarks and references
1	Di- and trichloroacetic acid	monochloroacetic acid	C (Hoechst)	indirect electrochemical process via the Pb^{2+}/Pb^0 couple in $ClCH_2COOH/H_2O/HCl$ (56:33:11) in the presence of 10 – 100 ppm $Pb(OAc)_2$	[426] reduction of overchlorinated products to the desired product in the synthesis of monochloroacetic acid
2	3,4,5,6-Tetrachloropicolinic acid	3,6-dichloropicolinic acid	C (Dow Chem.)	high-surface area (spongy) Ag-catodes activated by anodization in aqueous alkaline media in an undivided cell	[505, 506, 507, 508] product is a potent herbicide; production may be discontinued
3	2,2,2-Trichloro-1-(4-hydroxyphenyl)ethanol	2,2-dichloro-1-(4-hydroxyphenyl)ethene (elimination process)	C (Japan)	divided filter-press cell; Pb cathode in acidic $MeCN/H_2O$	[509] formation of p-hydroxyphenylacetic acid by hydrolysis
4	3-Chloromethyl-cephem derivative	3-exomethylene-cephem derivative	C (Japan)	at Pb cathodes in THF/ $H_2O/NH_4ClO_4/LiClO_4$	[510], [511]

By reductive elimination of halogen from 1,4-bis(bromo or dibromomethyl)benzene, *p*-quinodimethanes are formed. These polymerize in situ to give either poly-(*p*-xylylene) or by further reductive elimination poly-(*p*-phenylene-vinylene), which are both important conducting polymers [512], [513].

The cathodic cleavage of the silicon-chlorine bond in dichlorosilanes to synthesize polysilanes has been intensively studied. The commercialization by Osaka Gas Co., Japan, has been reported. This process is best performed in $THF/LiClO_4$ using Mg cathodes and sacrificial Mg anodes [514, 515, 516, 517, 518].

The cathodic cleavage of tetraalkylammonium groups is applied industrially in the formation of 1,4-dimethyl-2,3,5,6-tetrafluorobenzene from 1,4-bis(trimethylammoniomethyl)-2,3,5,6-tetrafluorobenzene dichloride making use of the selective cleavage of the benzylic carbon – nitrogen bond as compared with the methyl groups.

5.3.2.5. Electrochemical Coupling

C–C coupling reactions are in the center of organic syntheses to build up larger structures. Electrochemistry provides simple and efficient procedures for coupling reactions. The anodic Kolbe dimerization of carboxylates is one of the oldest electrochemical reactions [355] which is still important under technical aspects.

Coupling at the Anode.

Type 1:
$2\,RH \rightarrow R\text{–}R + 2\,H^- + 2\,e^-$ via cation radicals
Type 2:
$2\,R^- \rightarrow R\text{–}R + 2\,e^-$ via radicals

Type 1 describes the coupling of two electron-rich components like alkenes, aryl

olefins, enolacetates, enaminoesters, or enolethers [519]. Type 2 is the coupling of radicals obtained by electrooxidation of carbanions or carboxylates (Kolbe dimerization) [520].

The anodic coupling of compounds with an acidic methylene hydrogen has been developed technically by Monsanto Co. in the case of the tetramethyl ethane tetracarboxylate formation from dimethyl malonate. This reaction takes place in methanol in the presence of methoxide and of sodium iodide which acts as a redox catalyst [521].

The Kolbe dimerization of half esters (Brown – Walker reaction) has been applied on a pilot plant scale and also commercially in a number of cases by companies like BASF, Asahi Chem., Soda Aromatic, and other companies in Russia. Examples are the formation of dimethyl sebacate, dimethyl tetradecandioate and dimethyl hexadecanoate from monomethyl adipate, monomethyl suberate and monomethyl azelate, respectively. The reaction takes place at about 10 to 30 % neutralization of the acid at platinum anodes. The slow corrosion of the platinum is the major problem [403], [522].

Coupling at the Cathode.

Type 1:
$2\,–CH{=}CZ– + 2\,e^- + 2\,H^+ \rightarrow –CHZ–CH_2–CH_2–CHZ–$ via anion radicals
or
$2\,–CR{=}X + 2\,e^- + 2\,H^+ \rightarrow HX–CR–CR–XH$ via anion radicals
Type 2:
$2\,R^+ + 2\,e^- \rightarrow R–R$ via radicals

At the cathode, two electron-poor components can be coupled. While the dimerization of cationic species (type 2) has industrially only some importance in the coupling of pyridinium salts to give 4,4′-bispyridinium salts, type 1, the electrohydrodimerization (EHD) of electron-poor alkenes (–CH=CZ–) and carbonyl compounds (–CR=X with X = O; pinacolization), has found important applications.

The most important example of type 1 is the *electrohydrodimerization* of acrylonitrile to give adiponitrile developed by M. M. Baizer at Monsanto [357,358,359,360,361,362]. This process is commercialized by several companies on an overall scale of more than 300 000 t/a. While the early process required a divided membrane cell and a high concentration of tetraalkylammonium salts as supporting electrolyte, the modern process is run in a bipolar stack of carbon steel sheets, the cathodic side cadmium plated with a 2 mm interelectrode gap. Thereby, the concentration of the supporting electrolyte could be reduced to 0.4 % and the energy consumption was lowered to 40 % [346], [357,358,359,360,361,362].

Similarly, the highly selective hydrodimerization of maleic acid esters to yield butanetetracarboxylic acid esters or the corresponding tetracarboxylic acid has been developed by Monsanto [523].

Other EHD reactions which have been developed to the pilot plant stage are the *pinacolizations* of formaldehyde to give ethylene glycol (Electrosynthesis Co.) [524,525,526], acetone to yield pinacol (Diamond Shamrock) [527], *p*-hydroxybenzaldehyde to yield bis(4-hydroxyphenyl)ethane (Monsanto) [528], [529] and of *p*-hydroxypropiophenone to give 3,4-dihydroxy-3,4-bis(4-hydroxyphenyl)hexane (Sorapec, Glaxo, Reilly Ind.) [438]. The production of ethylene glycol by cathodic coupling of formaldehyde is piloted by two Canadian companies. It takes place in a divided cell at modified graphite electrodes in the presence of tetraalkylammonium salts. The economics of the chemical

and electrochemical alternatives are similar and depend strongly on the prices of the different feedstocks.

5.3.2.6. Bioelectrosynthesis

Since the mid-1990s, the field of bioelectrosynthesis has been growing considerably. In this approach, the chemo-, regio-, stereo- and enantioselectivity of redox enzymes is combined with the convenient supply of the redox equivalents by the electrode [530,531,532,533,534,535,536,537]. Thus, the redox state of the enzymes or their cofactors is controlled either by direct or mediated electrolysis allowing the development of continuous processes in flow-through systems. The enzymes, mediators (sometimes bound to water soluble polymers) and cofactors can be held back by ultrafiltration membranes or they may be immobilized at the electrode surface. Although these reactions are still developed only on the laboratory scale, industrial applications would have an interesting potential.

5.3.3. Organic Electrochemistry for a Cleaner Environment

The aspect of environmental protection by using electrochemical methods has gained more and more importance since the 1980s. Electrochemistry does not only offer new methods for waste treatment (curative environmental protection) but, even more important, also the possibility of preventing waste formation by using electrochemical production processes (preventive environmental protection). As the electron is mass-free, no spent reagents are formed. Additionally, regeneration of redox reagents can be performed electrochemically either in situ (in-cell method) or in a two-step process (ex-cell method) (see Section 5.3.1). This allows the use of environmentally unfriendly systems so that the pollution of the environment by spent reagents can be avoided. A typical example is the ex-cell electrochemical chromium(VI) regeneration in montan wax bleaching (see Section 5.3.2.3 [373], [374]). The control of the reaction and its automation in form of a continuous process can be achieved easily by proper selection of the electrical parameters. Thereby the development of closed systems is feasible. These aspects have been reviewed in [538], [539]. Three typical examples for preventive environmental protection will demonstrate the power of electrochemical procedures in this area:

1) The electroreductive restoration of monochloroacetic acid from di- and trichloroacetic acid (see Table 27, no. 1) [426] eliminates the necessity to treat the hazardous waste of these side products.
2) In the generation of methoxyacetic acid by anodic oxidation of methoxyethanol at a nickel oxide hydroxide anode the methoxyacetic acid can be liberated from its salt and the strongly alkaline aqueous electrolyte can be recovered by electrodialysis using bipolar membranes thus avoiding a high salt freight [540].
3) In the dying with vat dyes, the reducing agents, usually sodium dithionate, cannot be regenerated. Thus, a recycling of the dyebaths is not possible and the spent reducing agents lead to a high salt freight. This can be avoided if complexes of iron with triethanolamine or tri(isopropanol)amine are used as regenerable redox mediators. Processes especially for dying with indigo have been developed [541,542,543,544,545].

5.4. Experimental Factors and Techniques

The following experimental factors have to be taken into account for the application of an electrochemical reaction in synthesis:

- The choice of the electrolysis procedure- either working at controlled potential (potentiostatic or controlled potential electrolysis, CPE) or at a fixed current density (galvanostatic)
- The type of electron exchange
- The redox potential applied at the working electrode, if controlled potential electrolysis is selected
- The current density, if galvanostatic conditions are selected
- The charge consumption
- The composition of the electrolyte
- The type of electrode material

– The type of the electrolysis cell, divided or undivided, flow-through or beaker-type.

5.4.1. Solvent – Electrolyte Systems

The electrolysis medium (solvent and supporting electrolyte) influences the electrochemical process in many ways. The choice of the medium does not only largely determine the solubility of the compounds and the conductivity, but also the potential window for the desired transformation, the selectivity of the reaction, the chemical follow-up reactions, the separation of the products, the reaction at the counter electrode, the energy consumption and thereby also the economics of the process.

In general, the following requirements should be met by the electrolyte system:

1) It should have a high conductivity so that low cell voltages are possible at low concentrations of the supporting electrolyte. For this purpose, solvents of high dielectric constant are desirable.
2) The supporting electrolyte salts should be totally dissociated in the applied solvent. The dissociation of salts of larger ions is usually more readily obtained than that of salts of smaller ions.
3) The solubility of the components in the solvent must be sufficient. For technical applications, concentrations of the reactants of more than 0.5 M are desired to reach an economical current density. To improve the solubility, co-solvents can be used. Another possibility is the application of a two-phase system or an emulsion in the presence of phase transfer catalysts. A two-phase system has also advantages in product isolation and continuous electrolysis procedures. A typical example is the synthesis of *p*-methoxybenzonitrile by anodic substitution of one methoxy group in 1,4-dimethoxybenzene by the cyanide ion. The homogeneous cyanation system (acetonitrile, tetraethylammonium cyanide) [546] can be efficiently replaced by a phase-transfer system (dichloromethane, water, sodium cyanide, tetrabutylammonium hydrogensulfate) [547].
4) The stability of the electrolyte system at the applied potential or current density has to be high enough to ensure high current yields and to prevent electrolyte destruction. The stability of an electrolyte can be determined by measuring the foot potential in current – voltage curves. Limiting values can be found in most books on electroorganic chemistry [548].
5) For application in industry, the work-up of the product containing electrolyte must be easy and efficient. With capillary gap cells, the concentration of a supporting electrolyte may be so low that its recovery is not necessary from an economical point of view.

Other properties of the solvent-supporting electrolyte system may influence the reaction directly. For example, in aprotic solvents the cathodic limiting potential can be much more negative than in protic media, thus allowing the reduction of compounds with very negative potentials. However, under these conditions many compounds and electrogenerated intermediates tend to polymerize. Much cleaner reductions can often be obtained if small amounts of a proton donor are present to trap the reactive anionic intermediates. The nucleophilicity or electrophilicity of the electrolyte has also to be taken into account. Oxidations are very often running more smoothly and give cleaner products if at least small amounts of a nucleophile are present to trap cationic intermediates. In the case of reductions, it can be very helpful to trap the intermediates by the addition of electrophiles such as trimethylsilyl chloride, alkyl halides, carbonyl compounds, or carbon dioxide.

The electrolyte may also influence the product distribution. This can be demonstrated in the case of the side-chain oxidation of alkyl aromatics (see Fig. 73) [549].

Another well known example for the influence of the supporting electrolyte is found in the adiponitrile formation from acrylonitrile. If, for example, alkali metal salts are used as supporting electrolyte in the aqueous solution, the main product is propionitrile formed by hydrogenation of the double bond. This is favored over the dimerization because the metal ions which are accumulated within the Helmholtz layer are strongly hydrated so that the electrochemically formed

Figure 73. Influence of the product distribution by the nucleophilicity of the electrolyte

acrylonitrile anion radical is immediately protonated. To favor the dimerization, a tetraalkylammonium salt like $Et_4N^+EtOSO_3^-$ (early process) or $EtBu_2N^+(CH_2)_6N^+Bu_2Et(HPO_4^-)_2$ (modern process) has to be applied which is bulky and not hydrated, thus lowering the amount of water in the Helmholtz layer [357, 358, 359, 360, 361, 362].

It is obvious that water is the solvent of choice for industrial applications. Reasons besides the low price are its low impact on the environment, the good solubility of salts leading to highly conducting solutions, the easy control of the pH and the ease of controlling the reaction at the counter electrode (hydrogen or oxygen formation). On the other hand, because of solubility and selectivity reasons, organic solvents are often superior. Therefore, compromises have to be made. Thus, protic solvents, especially methanol, other alcohols, acetic acid, and mixtures of water or alcohols with other organic solvents are the next best choice. Dry aprotic solvents, often used in laboratory experiments, are generally not useful in larger scale applications. This is due to their high resistance, the instability of most membranes to these solvents, the difficulty in controlling the pH and the problem of controlling the reactions at the counter electrode for which purpose additives have to be used. Otherwise, polymerization, electrode passivation and the formation of side products are encountered. Sometimes these problems can be overcome by the addition of 5 to 10 % of water or methanol or by using emulsions or two-phase systems. Because of their value and their environmental impact, these solvent have to be recycled.

5.4.2. Electrodes

The choice of the electrode materials for the working electrode and also for the counter electrode influences the electroorganic process in many respects [550, 551, 552]. The material of the working electrode very often determines the selectivity of the electrode reaction – depending on the mechanism of the electron transfer (inner sphere or outer sphere) – and also the service life. The material of the counter electrode influences the type of the electrochemical process taking place at this electrode and thereby determines the electrode potential which develops at the counter electrode at a given current density. This affects directly the overall cell voltage and, thereby, the energy cost of the process. In addition, a controlled process at the counter electrode also influences the selectivity of the process by preventing undesired reactions of the products or starting materials at this electrode. By proper selection of the counter electrode and, thereby, the electrode process proceeding at this electrode, the application of a divided cell can be avoided in many cases. Thereby, also the cost

of the process can be diminished. In general, the electrode materials should meet the following requirements.

- Physical stability
- Chemical stability
- High conductivity
- Suitable physical form
- Suitable electrocatalytic properties
- Long service life
- Nonpolluting/noncontaminating
- Low cost
- No passivation/deactivation

Physical properties like physical stability, suitable physical form, and especially low electrical resistivity are essential. Massive, monopolar electrodes can be used in the case of good conducting metals (10^{-6} to $10^{-5}\,\Omega^{-1}\,cm^{-1}$) like Ag, Cu, Al, Zn, Ni, Cd, Fe, Pt, Pb, Ti, or PbO_2. For less conductive materials (10^{-4} to $10^{-3}\,\Omega^{-1}\,cm^{-1}$) like stainless steel, Hastelloy-C or carbon materials, a bipolar electrode arrangement reduces the current paths through the electrodes. Conducting polymers (conductance 2×10^{-3} to $10^{-2}\,\Omega^{-1}\,cm^{-1}$) have to be used as thin coatings on good conducting substrates.

The chemical stability criteria do not apply in cases where a dissolving anode (sacrificial anode) is selected to control the electrochemical process at the counter anode or to stabilize the products.

It is also necessary to divide the electrode materials into two categories:

1) Electrodes which are acting as pure electron acceptors or electron donors (outer-sphere electron transfer);
2) Electrodes which act as reagents or as heterogeneous redox catalysts (inner-sphere electron transfer).

The first category is made up mainly by the different carbon materials and the precious metals, if applied as working anodes. The second category contains metal and precious metal oxides mostly in the form of coatings on conductive substrates acting for example via oxygen transfer or hydride or hydrogen abstraction.

5.4.2.1. Cathodes

Cathodes as Working Electrodes. In aqueous media, cathodes used as working electrodes should have a hydrogen overvoltage which is high enough to prevent hydrogen generation. Table 28 presents the hydrogen overpotentials of some common electrode materials in 0.5 M aqueous sulfuric acid.

In nonaqueous, aprotic media the hydrogen overvoltage does not play a role. Commonly used cathode materials are lead, aluminum, copper, titanium, cadmium, silver, steel, stainless steel, Hastelloy-C (Ni – Mo – Fe or Ni – Mo – Cr) and all kinds of carbon.

On the other hand, if an electrocatalytic hydrogenation is the desired process, platinum group metal electrodes or coatings or high surface area nickel or nickel alloys can behave as hydrogen transfer catalysts via adsorbed hydrogen. This methodology has been widely used for the reduction of ketones, aldehydes, nitriles, alkenes, alkynes, Schiff bases, aromatics, nitro compounds, and carbohydrates [551], [553, 554, 555].

Cathodes as Counter Electrodes. In anodic oxidations, a controlled process has to take place at the counter cathode. Mostly the hydrogen evolution is selected. Hydrogen evolution can be supported by the application of precious metal electrodes or coatings thus lowering the electrode potential and, thereby, the cell voltage. To lower the cost of the materials, also Ni electrodes and coatings or different kinds of steel and also carbon of different types are commonly employed. Another possibility for controlling the process at the counter cathode and to lower the cathode potential is to use an oxygen consuming cathode (dispersed Pt on high area carbon). Nonstoichiometric titanium oxide (approximate composition Ti_4O_7), called Ebonex, has been proposed as a counter cathode. It is a very stable material and appears to be a good substrate for electrocatalytic layers [556], [557].

5.4.2.2. Anodes

Anodes as Working Electrodes. As more or less inert anode materials for working electrodes, platinum (Kolbe electrolysis) or all types of carbon and graphite are applied. Among carbon materials especially the three-dimensional

Table 28. Hydrogen overpotentials of common electrode materials in 0.5 M sulfuric acid

Electrode material	Pd	Fe	Pt	Ni	Sn	Pb	Zn	Hg
Hydrogen overpotential, V	0.00	0.08	0.09	0.21	0.53	0.64	0.70	0.78

materials like carbon felt and reticulated vitreous carbon are of interest for applications in which the current density has to be kept low.

Very often, metal oxide electrodes, mostly supported on a conductive carrier, can be applied as anodes. In most of these cases, the metal oxides are not inert but act as electrocatalysts for instance, via oxygen transfer (PbO_2, mostly supported on Ti or on Pb) or hydrogen abstraction (NiOOH on Ni) [469,470,471,472,473], [558]. Other electrocatalytic electrodes are Fe_3O_4, RuO_2 on Ti (dimensional stable anode, DAS), Co_3O_4, IrO_2 on Ti, MnO_2 on Ti or Ni/Co spinels [559]. Conducting ceramics may also be applied as catalytic anodes as it has been shown for Cr_2O_3 on Ti [560]. However, in most of these cases, because of the limited number of active centers on these metal oxide electrodes, the current densities have to be kept low and therefore high surface area electrodes have to be developed. The application of such oxide electrodes has by no means yet been fully developed to their expected potential. One major problem with anodes is their possible corrosion.

Figure 74. Anodic current – voltage curves for four anode materials in aqueous Na_2HPO_4 with 25 mM quaternary ammonium salt, equilibrated with AN/ADN (25 : 75)
a) DSA (RuO_2 and TiO_2 on titanium metal); b) Carbon steel; c) Pb/PbO_2; d) Pt
Courtesy of *Hydrocarbon Processing* [397].

Anodes as Counter Electrodes. For cathodic reductions, a controlled electrode process has to take place at the counter anode. This allows very often the application of an undivided cell and the lowering of the cell voltage. Most commonly, oxygen evolution is selected as the process at the counter anode. Thus, all materials with a low oxygen overvoltage are favorable. These include IrO_2 on Ti, PbO_2 on Pb or Ti, RuO_2 on Ti (DSA), and carbon steel (mild steel) or iron oxide on iron (low cost alternative to DSA as developed for the adiponitrile process [357,358,359,360,361,362] as shown in Figure 74. Also the nonstoichiometric titanium oxide, Ebonex, has been proposed as counter anode (see page 96).

Another possibility especially when aprotic solvents have to be used is to choose electrode materials that dissolve in the process (sacrificial anodes like Al, Mg, Zn, Sn [420,421,422,423], [561], [562]) with or without the accompanying formation of organometallic intermediates. Such a process clearly adds to the cost of the process and is, therefore, most likely only justified for high value added conversions.

5.4.2.3. Other Factors Influenced by the Electrode Material

The electrode material can also influence the product distribution as shown in the Kolbe electrolysis of carboxylates. With platinum anodes, the Kolbe dimerization of the intermediate radicals predominates strongly. At carbon anodes, however, further oxidation to the carbenium ion (Non-Kolbe reaction or Hofer – Moest reaction) becomes the main pathway.

In the anodic olefin oxidation the electrode material plays an important role as well. The oxidation of enolethers at platinum anodes mainly leads to the dimethoxylation product [563] while the application of graphite anodes favors the additive dimerization [519].

Another typical example can be found in the cathodic reduction of acetone, the outcome of which is dramatically changed when different electrode materials are used.

The adsorption of intermediates is also a function of the electrode material. All these effects of electrode materials will strongly influence the outcome of a reaction.

Three factors may influence the long-term behavior of electrodes:

1) Poisoning of the electrodes like, for example, deposition of traces of Fe, Cu or noble metals on cathodes of high hydrogen overpotential, thus lowering the potential of hydrogen evolution. This can be avoided by careful purification of the electrolyte.
2) Filming of the electrode by deposition of insulating polymeric byproducts. This may be avoided by interruption or reversal of the current, by mechanical or chemical cleaning of the electrode surface, or by introduction of a redox catalyst (mediator, indirect electrochemical process).
3) Corrosion of the electrodes. This may be avoided by proper selection of the electrode material, the electrolyte or by periodic replacement of the electrode stacks.

5.4.3. Electrochemical Cells

The electrochemical reactors are in the heart of an electrochemical process. The fundamentals of the cell design have been discussed in detail [346], [564,565,566,567,568] (see Chap. 3).

5.4.3.1. General Considerations

For larger scale application, especially in industry, it is necessary to lower the energy consumption as much as possible. The energy consumption (kW h/kg) is the product of the cell voltage U_C and the consumed charge:

$$\text{Energy Consumption} = (nF/3.6\,\Phi M)U_C\ 10^{-6}$$

where M is the molar mass of the product in kilograms per mole, Φ is the fractional current efficiency for the desired product, n is the number of electrons consumed for the formation of the product, and F is the Faraday constant in coulombs per mole.

The cell voltage (for a reduction) is given by the following equation:

$$U_C = E_C - E_A - U_\Omega$$

E_A and E_C are the active potentials at the electrodes (sum of the thermodynamic potential and the required activation overpotential), while U_Ω is the sum of the ohmic voltage drops IR at the resistances of the electrolyte, the diaphragm, and the circuit. The solution ohmic voltage drop is given by the equation

$$U_{\Omega\,\text{Soln}} = IR = r\,d\,j$$

Here, r is the resistivity of the electrolyte, d the interelectrode gap and j the current density (current divided by the electrode area).

Thus, for minimizing the energy consumption, it is mainly necessary to reduce the cell voltage. This can be done by the following measures:

1) To keep the $U_{\Omega\,\mathrm{Soln}}$ as low as possible, the interelectrode or electrode-membrane gap should be minimized. The electrode may even touch the membrane as in zero-gap or solid polymer electrolyte (SPE) cells. Because the resistivity r of organic electrolytes is much higher than that of inorganic electrolytes, the minimization of the ohmic drop is especially important in these cases. The electrolyte resistance is linearly dependent on the electrode distance d. Therefore, this distance should be as small as 0.1 – 1.0 mm and a diaphragm should be avoided (undivided cell), if possible. These conditions are best fulfilled by capillary gap cells with gaps of 0.1 – 0.2 mm. In this case, also the concentration of the supporting electrolyte can be very small.
2) The reaction at the counter electrode should be chosen in such a way that the reversible cell voltage is minimized (see Section 5.4.2).
3) The overpotentials at both electrodes should be reduced for example by using electrocatalysts or adequate electrode materials.
4) If possible, the cell should be undivided to minimize the construction cost and also the energy consumption due to the resistivity of the separator. The application of a controlled reaction at the auxiliary electrode taking place at low potential allows for the use of undivided cells in many cases. For oxidations, the cathodic process at the auxiliary electrode may be a proton reduction under formation of hydrogen or the reduction of oxygen. For reductions, the anodic process may be the formation of oxygen from water, for organic solvents the application of sacrificial anodes, or the oxidation of formate or oxalate to produce carbon dioxide [569] (see also Section 5.4.2). Besides this "least damage" approach, the possibility exists to carry out a synthesis at each electrode. This so-called "*paired electrosynthesis*" seems to be very attractive since the process cost can be spread over two products. However, it seems to be very difficult to find optimal conditions for both electrode processes. Also, work up is often more difficult and the two products are always formed in the same amount which may cause marketing problems. While many laboratory studies have been performed (for examples see Section 5.3) the commercial application has been established only recently. The problems which are involved are described by Baizer [447] for the paired synthesis of sorbitol (cathode) and gluconic acid (anode) from glucose. Other examples have been indicated in Tables 20, 21, 22, 23, 24, 25, 26, 27. A special case of the paired electrosynthesis is the formation of the same product at anode and cathode (200 % electrolysis cell). This principle can be accomplished by the direct or indirect electrochemical generation of hydrogen peroxide at the cathode which then is used as a chemical oxidant (oxidation at the cathode) forming the same product which is also obtained at the anode (Fig. 75). Several laboratory examples have been published [570, 571, 572] but practical applications have not yet been accomplished.
5) The electrode surface should be as large as possible to increase the space – time yield.

Besides the energy consumption, the electrolysis cell must be optimized for a high space – time yield or weight of product per unit time per unit volume of the reactors. It is given by the following equation:

$$STY = (M/Fn)\Phi\, j\, A/V$$

in which M is the molar mass of the product, n the total number of the exchanged electrons for the formation of the product, F the Faraday constant, j the current density, Φ the current efficiency, A the electrode area and V the cell volume. Thus, the space – time yield can be optimized by using a high area per unit cell volume (high surface area electrodes such as three-dimensional electrodes, capillary gap cells). To obtain a high current density, not only a high concentration of reactant is necessary but also an optimum mass transport. The latter may be obtained by using high flow rates, turbulence promoters, and/or electrode movement.

5.4.3.2. Cell Design

For laboratory cells, the minimization of the energy consumption and the optimization of the space – time yield are not equally as important. It is more important that the different reaction parameters like electrode materials, diaphragms,

Figure 75. Paired electrosynthesis, special case of the formation of the same product at anode and cathode

Figure 77. Schematic diagram of a parallel plate and frame cell with bipolar electrode arrangement

and the working potentials can be varied easily. For electrolyses under potential control, a three-electrode construction has to be used, which is schematically shown in Figure 76.

For technical applications, CPEs are undesirable because of technological problems, high cost and a nonstationary product formation due to changing current densities. Instead, in industry controlled current electrolyses using normal and less expensive d.c. power supplies are the only established methods. In this way, the current density can be fixed leading to a stationary formation of the product. The selectivity can be controlled by the proper selection of the current

Figure 76. Schematic representation of an electrolysis cell (three-electrode construction)
W = working electrode; Aux = auxiliary or counter electrode; R = reference electrode; Q = coulombmeter; D = diaphragm, if necessary; CS = current source;

density and the substrate concentration which can be fixed to the desired value by using a continuous process. For this purpose, it is desirable that the whole electrode surface operates at the same optimum current density so that also an even potential distribution at the electrode surface is obtained. Thus, the whole electrode surface is productive and has the same rate of chemical change. At the same time, the formed intermediates find the same chemical environment for follow-up reactions. This condition is most easily fulfilled by using parallel plate cells which is therefore the most popular cell design. To obtain optimum space – time yield (see above), it is necessary to optimize the ratio of electrode area to cell volume. The three most important cell designs with parallel arrangement of the electrodes are arranged in the order of minimizing the interelectrode gap: the parallel plate and frame cells (Fig. 77); the capillary gap cell (Fig. 78) and the SPE cell, which is constructed like a proton exchange membrane fuel cell (PEMFC).

Figure 78. Capillary gap bipolar disc – stack cell

Parallel Plate and Frame Cells. The parallel plate and frame cells have interelectrode gaps of between 1 and 12 mm. The electrodes can be connected either in a monopolar or in a bipolar fashion (Fig. 79). For *monopolar connections*, the electrical contact has to be made to each electrode and thus both faces of the electrode will have the same polarity. The d.c. rectifier has to supply the cell voltage plus the cell current multiplied by the number of cells (interelectrode gaps). Therefore, a low voltage and a high current has to be supplied. In addition, as the current path through the electrodes is rather long, electrodes with a high conductivity have to be used. In *bipolar connections*, contact is only necessary to the end plates. The other electrodes are polarized in the electric field. The two faces of the electrodes, therefore, have different polarities. The d.c. rectifier now has to supply the cell current plus the cell voltage multiplied by the number of cells (interelectrode gaps). Thus, the current is used n times with n being the number of cells and, therefore, a lower current but a high voltage has to be supplied. As the current path through the electrodes is small, also less conducting electrode materials can be used.

Due to an active development since the late 1970s, reliable parallel plate and frame electrochemical cells of all sizes from laboratory scale to pilot scale up to production scale in divided or undivided form and with monopolar or bipolar connection are now commercially easily available. Suppliers are companies such as ElectroCell AB [573] (Micro Flow laboratory cell with 10 cm^2 electrode area for one electrode; MP Cell with 0.01 to 0.02 m^2; ElectroSyn Cell with 0.04 to 1.04 m^2; ElectroProd Cell with 0.4 to 16 m^2), ICI [574] (FM01-LC laboratory cell with 64 cm^2 for one electrode; FM21-SP Cell with 0.21 to 12.6 m^2 electrode area; FB cell family for bipolar electrode arrangements); Electrocatalytic Ltd. [575] (Dished Electrode Membrane Cell = DEM with single electrode areas of 0.05 m^2, 0.175 m^2, and 1.0 m^2) and Reilly Tar and Chemical [576]. Therefore, at least in the case of specialty chemicals or fine chemicals, the development of new cells for a process is not anymore necessary. The Mark II process for the formation of adiponitrile [361, 362, 363, 364, 365] from acrylonitrile is now performed in an undivided parallel plate cell with a cadmium plated steel cathode and an interelectrode gap of 2 mm.

Capillary Gap Cells. To reduce the interelectrode gap below 1 mm, undivided bipolar capillary gap cells are the best choice. In this way, poorly conducting solutions or low concentrations of the supporting electrolyte can easily be used. The most successful design has been developed by BASF (Fig. 78) and consists of a bipolar stack of horizontal circular rounds usually machined from graphite or graphite-filled

Figure 79. Electrical connection for monopolar (A) and bipolar (B) electrode arrangements

plastic discs separated by thin insulating spacers. The liquid is pumped radically in the 0.5 – 1 mm gaps [577,578,579]. Such cells are easily machined and are available in sizes from the laboratory scale up to the technical scale. The commercial production of benzaldehyde dimethylacetals from toluene derivatives and also the dimethoxylation of furan are performed in these cells at BASF. A concentric capillary gap cell made from a stainless steel tube (pipe) as cathode and an inner concentric graphite rod as anode was also developed [580]. It is very easy to construct but has a rather low space – time yield. Capillary gap cells can also be constructed in a parallel plate version using square vertical electrode plates [581].

Solid Polymer Electrolyte Cell. The SPE cell reduces the interelectrode gap even further. In this design, two porous electrode layers are in direct contact with a solid polymer electrolyte, usually an ion-exchange membrane like Nafion with a thickness of 20 to 50 µm. Thus, a supporting electrolyte is not required and product separation is made very easy. This concept has been suggested earlier [582], [583]. However scale-up and stability were problematic. More recently, it was shown that the pretreatment of the ion-exchange membrane is very important for the success of this cell design. For example, the pretreatment of Nafion membranes in DMF at elevated temperature leads to a successful application for the anodic α-methoxylation of DMF [584,585,586,587,588,589]. Besides amides, also furan could be methoxylated efficiently. Even cycloaliphatic ethers such as tetrahydrofuran can be methoxylated at a high current efficiency using only methanol as solvent [589]. The successful application of an electrode stack similar to that of the concentric capillary gap cell seems to open up the way to a technical application.

Cells with Sacrifical Anodes. A technical fenoprofen synthesis on the pilot scale was developed by SNPE based on the reductive carboxylation of chloroethyl diphenyl ether under cleavage of the carbon-halogen bond using a sacrificial magnesium anode [420,421,422,423], [561], [562]. For this purpose, a special cell for the application of the sacrificial anode was designed. This so-called "pencil-sharpener electrochemical cell" (Fig. 80) consists of a cylindrical magnesium bar of 40 cm diameter as anode. The cathode is a stainless steel cone which is 1 m high. The anode is pressed onto the conical cathode by its own weight. To prevent contact between the two electrode, the cathode surface is covered by a conical polyethylene grid. Due to the different current densities, the electroerosion is higher where the interelectrode gap is narrower. Thus, the anode is automatically electromachined into a pencil-like shape fitting closely to the cathode with an interelectrode gap of a few millimeters. The electrolyte is pumped between the two electrodes with the polyethylene grid acting as a turbulence promoter. The pilot unit has a cathode area of 1.2 m^2.

Figure 80. Pencil-sharpener electrolysis cell with sacrificial anode

Cells with Three-Dimensional Electrodes. If dilute solutions have to be electrolyzed at an acceptable rate or if reactions which show selectivity only at low current densities have to be carried out, three-dimensional electrodes must be considered. They give a high area:unit volume ratio under good mass transport conditions [590], [591]. However, the current distribution is not always homogeneous and has to be taken into account. Three-dimensional electrodes can be formed by using packed or fluidized beds of particulate electrodes or by using three-dimensional electrode materials such as carbon felts, reticulated materials, metal foams etc.

A special type of three-dimensional cell is called "Swiss Roll" cell. It has been developed for the oxidation of diacetone-L-sorbose to diacetone-2-keto-L-gulonic acid as a vitamin C precursor. It consists of a stainless steel net cathode and a nickel net anode separated by a spacer material such as a polypropylene net. The entire arrangement is rolled up and forced into a metal pipe (Fig. 81). Cells with a diameter of 1 m and a total anode and cathode area of 200 m^2 have been used in a pilot plant by Hoffmann-La Roche [469,470,471].

Figure 81. "Swiss-Roll Cell" for the application of NiOOH-electrodes (a = steel net cathode; b + d = polypropylene net; c = nickel net anode; e = current feeder)

5.5. Economic Aspects

Electrons are by far the least expensive reagents. On a molar scale they are in the same low cost range as hydrogen or oxygen in an integrated chemical plant [592]. The costs of various reducing agents are compared in Table 29.

It is frequently said that the fact that only a relatively small number of electroorganic processes has been realized in industry is due to the high investment and energy costs. Degner [363] and others point out that this is a prejudice. For processes of up to 10 000 t/a, the energy costs for the electrolysis are in most cases between 6 and 15 % of the total manufacturing costs, in rare cases like in processes using low molecular mass starting materials, they can reach up

to 25 %. The investment for the electrochemical part of the equipment, usually, is only 30 to 40 % of the total investment, the proportion for the cell being only about 2 % of the total investment if an undivided cell is used and may increase to a maximum of 15 % for a divided cell.

The prerequisites for the industrial application of an electroorganic process are listed in Table 30 [363], [403]. However, these data may be too general. To evaluate the different cost factors for electroorganic processes more exactly, it is necessary to divide the products into three classes [367].

1) Commodity chemicals (above 10 000 t/a)
2) Fine chemicals (100 – 10 000 t/a)
3) Specialty chemicals (< 100 t/a)

As Figure 82 shows energy consumption is a dominant factor only in very large scale processes. In these cases, also the cost of electrodes and membranes (cell components), respectively their service lives and reliabilities are very important. Also, the cell costs are a contributing factor. In contrast, for specialty chemicals the cost of the starting material is dominating while the energy cost is almost negligible. Thus, the selectivity of the process is important. Therefore, even more costly cell components or their early replacement are easily tolerated if this helps to increase the selectivity. For fine chemicals the cost of the starting materials and the investment in cells is usually more important than the energy cost. In all cases, the ease of the product isolation and electrolyte recovery together with the nature and level of byproducts are critical.

Therefore, in contrast to some frequently heard conclusions, large scale electroorganic processes are not ruled out. To meet the requirements, however, is not easy. The Monsanto process for the electrohydrodimerization of acrylonitrile to adiponitrile demonstrates that it is possible. Another potential, large scale process which has been developed up to the pilot plant is the electrohydrodimerization of formaldehyde to give ethylene glycol. The economics of the chemical pathway via ethylene oxide and the electrochemical routes are similar and the preference for the chemical or the electrochemical pathway is mainly a result of the relative prices of the different feedstocks, ethylene or formaldehyde, which might differ from company to company.

It has been pointed out [592] that the ratio of the total manufacturing costs to the cost of the d.c. power of successful electrochemical processes relates to the plant capacity in tons per year in a somewhat hyperbolic fashion. Thus, for commodities in the range of 100 000 t/a the ratio of manufacturing costs to d.c. power costs is about 2, for 5000 t/a capacity it goes up to 3, for 1000 t/a to 4 and for 100 t/a it reaches 8.

The following factors influence the commercial success of an electrosynthetic process. Only some of the factors are inherent to the electrochemical methodology and they have been discussed in more detail above.

Factors which are common to all processes but are influenced by the electrochemical methodology:

1) The cost and availability of the starting materials
2) The sale price for the product
3) The market for the product
4) The patent situation
5) The performance of alternative processes
6) Safety considerations (hazards are usually low with electrochemical processes due to their mild conditions)
7) Environmental considerations (electrochemical processes are usually environmentally friendly)
8) The quality of the product depending on the nature and quantity of impurities (electrochemical processes often produce purer products)
9) The ease of product isolation (separation form supporting electrolyte sometimes causes problems)
10) The material yield and/or selectivity of the reaction

Factors which are inherent to the electrochemical methodology:

1) The energy consumption in kW h/t (optimization has been discussed in Section 5.4.3)
2) The cost and lifetime of the cells and cell components like electrodes and membranes
3) The strategy for the counter electrode reaction leading to a clean and balanced overall cell chemistry and also to lower the energy consumption
4) The current density which determines the space – time yield and thereby the plant production rate

Table 30. Preconditions for the industrial application of an electroorganic process [363], [592]

	1988	1995
High selectivity and product yields	> 80 %	no environmentally problematic byproducts
High current efficiencies	> 50 %	> 70 %
Energy (electricity) consumption per kilogram of desired product	< 8 kWh/kg of end product	
Concentration of the end product in the electrolyte	> 10 %	
Service life of the electrode	> 1000 h	> 4000 h
Membrane lifetime (divided cell)	> 2000 h	> 8000 h
Simple work-up of the electrolysis products		
Simple removal and recycling of the electrolyte		low emissions

Figure 82. Importance of factors influencing the cost of electroorganic processes in dependence of production scale

5) The stability and reproducibility of the process (electrode poisoning and passivation, electrode corrosion)
6) Company experience of electrolytic processes
7) Company interest in performing related electrochemical reactions in the same plant

1. Introduction

Two luminescence phenomena are of major technological significance: cathodoluminescence, which is widely used in cathode ray tubes (e.g., television screens), and *electroluminescence.* The latter owes its importance to two semiconductor photoemission applications, namely, *light emitting diodes* (*LEDs*) and *laser diodes* (*LDs*). Electroluminescence refers to the process of radiation emission by a suitable material, a luminophor, following excitation induced by electronic processes, such as an applied voltage.

Electroluminescence was first observed in 1907 by H. J. ROUND at the electric point contact of a silicon carbide crystal. This effect was rediscovered in 1921 by O. V. LOSSEV, and the excitation of zinc sulfide in an alternating electric field, carried out in 1935 by G. DESTRIAU, revealed a photoemission process that is still of in significance today for display elements. These applications of electroluminescence and the material questions are treated under → Display Technology.

The monochromatic radiation discovered by LOSSEV had an energy hc/λ, close to that of the applied voltage, which enabled him to classify this process as the inverse of the Einstein photoelectric effect. In 1951, K. LEHOVEC explained the radiation observed as a result of the recombination of injected minority carriers – electrons and holes – in semiconductor diodes, an effect predicted in 1947 by W. SHOCKLEY in connection with the transistor. This theory laid the basis for the use of special semiconductor diodes as photoemissive luminescence diodes.

Normally semiconductor diodes are used as rectifiers, since they allow or inhibit the flow of current, an effect based on the properties of the *p-n* junction (→ Semiconductors), which consists of two adjacent regions of a semiconductor crystal doped with donors or acceptors, thus allowing conduction by electrons (*n*) or holes (*p*). *Donors* are impurity atoms on lattice sites that, compared with the replaced atom, have an extra electron in their outer shell. *Acceptors* lack one electron and therefore are able to capture a valence electron. For details, see → Semiconductors.

Only specific energy states are permitted for the electrons in a semiconductor. Because the distances between the atoms in the solid semiconductor are small, the electrons of the outer shells interact – both ground state and excited states degenerating into broad energy bands. The ground-state band contains the electrons that bind the atoms in the crystal lattice; therefore, it is called the *valence band.* The excited states contain the additional electrons supplied by the donors. These electrons move freely in the crystal; therefore, the corresponding band is called the *conduction band.* In a similar way, the valence electrons captured by the acceptors produce in the valence band empty electron states that can move freely in the crystal as positively charged *holes.*

A *barrier layer* without charged carriers is set up between the *n* and *p* regions of a *p-n* junc-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a09_255

tion on account of diffusion equilibrium. Holes or electrons can be injected through the barrier layer with a forward voltage, i.e., by applying the positive pole of a potential to the *p* region and the negative pole to the *n* region (Fig. 1). The result is a *transition zone* that simultaneously contains electrons in the conduction band and holes in the valence band.

Figure 1. Structure of a simple semiconductor luminescent diode: ⊖ electrons, ⊕ holes

This state is naturally unstable, and the system tends to return to equilibrium. In this equilibration process, the electrons of the conduction band recombine with the holes of the valence band, and the energy corresponding to the gap E_g between the bands is usually absorbed by the crystal lattice as vibrational motion. In some binary and quasibinary mixed semiconductors composed of atoms of valencies III and V or II and VI, both with tetrahedral structure, or IV and VI with an octahedral structure, the recombination process for additional carriers leads directly to the emission of a light quantum (photon) without involvement of the lattice atoms. Especially for some compositions of III – V materials, this process takes place with a high quantum efficiency, i.e., the number of light-emitting processes per injected electron is close to unity. In this case, the photon energy is given by

$$h\nu = hc/\lambda = E_g$$

h = Planck's constant, ν = frequency of the light, c = speed of light, and λ = wavelength of the light

If these processes run spontaneously, i.e., in an uncorrelated way, the crystal or diode emits *incoherent light.* In this context, the term light also includes the electromagnetic radiation in the infrared and ultraviolet regions adjoining the visible spectrum insofar as such radiation can be generated by an electroluminescent mechanism. If a Fabry-Perot resonator is created, e.g., by arranging two plane crystal surfaces parallel, as a reflector pair, then a large part of the generated light is reflected back into the excitation region of the crystal, where it builds up such a high intensity between the reflecting surfaces that further radiative recombination processes are induced. The light generated is in phase with the existing light wave, thus amplifying its intensity and stimulating further radiative recombination. The resulting laser light is *coherent,* extremely monochromatic, and may have an exceptionally high energy intensity (→ Lasers).

Table 1. Direct semiconductor materials for electroluminescent and laser diodes: band-to-band transitions

Crystal system	Emission wavelength, μm
Binary III – V compounds	
GaAs [*1303-00-0*]	0.84 – 0.90
InP [*22398-80-7*]	0.91
GaSb [*12064-03-8*]	1.50
InAs [*1303-11-3*]	3.10
InSb [*1312-41-0*]	5.40
Ternary III – V compounds	
InN–GaN	0.36 – 0.62
GaAs–AlAs, Al : Ga<0.85	0.63 – 0.90
GaAs–GaP, P : As<0.82	0.64 – 0.90
InP–GaP, Ga : In<1.63	0.67 – 1.10
GaAs–GaSb	0.90 – 1.50
InP–InAs	0.91 – 3.10
GaAs–InAs	0.84 – 3.10
InAs–InSb	3.20 – 5.40
Quaternary III – V compounds	
(Ga, In)(P,As)	0.58 – 1.30
(Ga, In)(As, Sb)	0.90 – 2.20
(Ga, In, Al)P	0.62
IV – VI compounds	
PbS [*1314-87-0*]	4.30
PbSe–PbS	4.30 – 8.50
PbTe [*1314-91-6*]	6.80
PbSe [*12069-00-0*]	8.50
PbTe–SnSe	10 – 12
PbTe–SnTe	6.5 – 28

Ever since the discovery in 1962 of the high quantum efficiency, almost 100 %, of gallium arsenide diodes, which emit monochromatic infrared radiation, the use of electroluminescent semiconductors has made rapid strides, leading to the rapid development of *light emitting diodes* (*LED*), which supply incoherent light, and *laser diodes* (*LD*), which supply coherent light. These light emitting diodes and laser

diodes play a major part in implementing communication between man and machine with luminous red, yellow, green, and blue indicator lamps and optoelectronic displays for numerals and other characters. Semiconductor diodes operating at room temperature have been successfully used to generate light of wavelengths between 5.4 and 0.36 μm (Table 1). If lower operating temperatures are possible, this range can be extended to 28 μm using the chalcogenides of lead and tin.

The development of special laser diodes is still in full swing. Their principal uses in optical signaling and communications are as coherent light sources for light transmission at 0.8 μm and 1.55 μm for the absorption windows in quartz fibers and at 1.3 μm for the dispersion windows in quartz fibers (→ Glass). For absorption windows, interest centers on monomode-emitting laser diodes adapted to monomode fibers, which are preferred because of their high transmission bandwidth. Outside the dispersion window, diodes with a corrugated waveguide structure are required – they have a very narrow emission line because of their internal distributed feedback (DFB), thus experiencing little spread when traversing the fiber route. Such DFB lasers are needed particularly in integrated optics (IO) and optoelectronics (OEIC) for monolithic integration with detector, amplifier, and switching elements, which are usually developed on the basis of gallium arsenide or indium phosphide substrates. The lacking long-term stability of most semiconductor lasers, which was initially a major problem, has now been largely solved or at least is seen to be solvable.

2. Physics of Light Emission in Semiconductors

The recombination of electrons and holes can take place with or without photoemission, corresponding to the various permitted transitions between energy states.

The electronic states of the pure semiconductor are degenerated to state bands. These bands comprise the permitted energy states with various electron momenta *p*. An important role is also played by more or less localized states that result from lattice defects or the inclusion of impurity atoms. Figure 2 shows regions in the band structures (of gallium arsenide, GaAs, and gallium phosphide, GaP) that are important for the emission of light through recombination of electrons and holes. *Gallium arsenide* and *gallium phosphide* are representative materials for the different light-producing processes involved in electroluminescent devices. The permitted energy states are plotted against the momentum vector p for characteristic crystal orientations. Excess electrons are introduced into the conduction band E_c and holes into the valence band E_v, e.g., by optical excitation of valence electrons or by current carrier injection via a *p-n* junction. In GaAs, these can recombine *directly* where the momenta coincide (Γ_1 on E_c and Γ_8 on E_v); otherwise, a third collision partner is necessary. The direct process, which is always associated with the emission of light, takes place only in *direct semiconductors*, i.e., those having a band structure like GaAs (see Table 1).

Indirect transition, demonstrated in Figure 2 for GaP, can take place in all materials, usually yielding no light. If the energy is initially transferred to a free carrier in the conduction or valence band or to a weakly localized charged imperfection, lattice vibrations are generated through interaction with the lattice atoms. So far, radiative indirect transitions of high efficiency have been achieved primarily by the inclusion of isoelectronic imperfections or by use of ultrapure GaP crystals. Isoelectronic impurity atoms, e.g., nitrogen, can replace the phosphorus atoms, or special binary "molecules," e.g., zinc – oxygen pairs, can replace adjacent gallium – phosphorus pairs without affecting the charge equilibrium (Table 2). Such uncharged imperfections may lead to a more localized binding of an electron whose momentum, due to the uncertainty principle, is blurred over the entire momentum range (E_i in Fig. 2). Radiant electron transitions from the conduction (X_1 on E_c) to the valence band (Γ_8 on E_v) are now possible via these or other states that lie in the forbidden energy band.

Which of these two recombination processes predominates in a given case is determined by the transition probability. For nonradiative transitions via charged imperfections, this probability increases with the density of the imperfections, lowering light efficiencies at high doping density even in direct semiconductors. In semiconductors with a small gap between the valence

Figure 2. Important photoemission regions of the energy band structure for GaAs, a direct semiconductor, and GaP, an indirect semiconductor, showing $\ominus \rightarrow \oplus$ light emissive recombination processes

Table 2. Indirect semiconductor materials for luminescent diodes: term transitions

Crystal	Doping	Wavelength, µm	Emission color	Luminous efficacy, lm/W
GaP [*12063-98-8*]	Zn, O pairs	0.69	red	3.0
GaP	N	0.57	green	4.5
GaP	N, N pairs	0.59	yellow	0.5
GaAs–GaP, P : As>0.82	N	0.55 – 0.67		
$GaAs_{0.35}P_{0.65}$	N	0.63	orange	0.9
$GaAs_{0.15}P_{0.85}$	N	0.59	yellow	0.9
GaN [*25617-97-4*]	Zn		blue	0.03
ZnS [*1314-98-3*]	Al		blue	0.05
SiC [*409-21-2*]	Al, N pairs		blue	0.01

and conduction band, nonradiative recombination processes predominate even at room temperature, so that luminescent diodes with long-wavelength emission have practical efficiencies only at low temperature.

A laser effect occurs at very high excitation, i.e., when the densities of the electrons and holes exceed a threshold in the excited region. The interaction between the crystal and the emitted light changes from the normally predominant absorption effect to a state of stimulated emission.

The wavelength of light attainable with luminescent diodes would be restricted by the intrinsic values of the bandgaps E_g of known semiconductor materials and by the attainable electronic states in the forbidden band caused by known dopants were it not possible to realize continuous series of mixed crystals with continuous values of the bandgap E_g, as is shown in Figure 3 for III – V semiconductor materials.

Table 1 lists the most important photoemissive semiconductor materials and their mixed crystal series along with the light wavelength attainable in the direct range of the band gaps. Indirect materials (Table 2) can be used for other colors when isoelectronic dopants are present. In addition, the emission lines of GaP-based diodes can be continuously shifted toward longer wavelengths by partial replacement of P by As.

3. Manufacture of Crystal Layers for Luminescent Devices

The most important aspect of manufacturing luminescent diodes is to set the desired wavelength. In practice, however, the wavelengths in Table 1 may be set only under certain conditions.

Figure 3. Lattice constant vs. wavelength (bandgap energy) for important III – V semiconductors
Solid curves show compounds with direct recombination; dashed curves show regions of indirect transition. Binary substrates that can be used for lattice-matched layer growth are indicated by the straight horizontal lines.

The nonbinary crystals, i.e., mixed crystals, cannot be obtained by the procedures used for manufacturing bulk binary crystals. Instead, mixed crystals must be grown by epitaxial processes on binary substrates with optimally matched lattice constants, this being especially important for laser diodes. However, the choice of possible substrates is extremely limited. In Figure 3, the lattice parameters for GaAs, InP, InAs, and GaSb are plotted as horizontal lines. The concentration of Al can be freely selected only in the AlAs – GaAs system; in all other ternary systems, only small regions in the vicinity of one of the binary components are permissible. The only way of obtaining other emission wavelengths is to use quaternary mixed crystals to avoid the enormous lattice distortions that are the main cause of aging, especially in laser diodes, and thus the drastic reduction of the emission efficiency during operation. A number of deposition procedures are available for epitaxial growth of binary, ternary, and quaternary layers on suitable substrate crystals.

Epitaxy from a metal melt containing the required components in the correct composition is the most advantageous approach in terms of equipment outlay. This process, known as *liquid-phase epitaxy* (*LPE*), uses the trivalent metal components, e.g., Ga or Ga – Al, as solvents for the pentavalent components. Thus, a Ga – Al melt saturated with As or P is applied onto a GaAs or GaP substrate at a high temperature or generated by dissolving a thin layer of the substrate. If the system is allowed to cool slowly, an epitaxial semiconductor layer grows until the remaining melt is pushed away. This process can be carried out several times in succession, with variously doped melts, or the various doping materials can be successively introduced via the gas phase.

Liquid-phase epitaxy has proved effective for Si-doped GaAs diodes, in which the doping character of the silicon changes at a specific temperature during the cooling process from a predominantly donor mode to a predominantly acceptor mode, resulting in the *p-n* junction required for charge carrier injection. Liquid-phase epitaxy is also used predominantly for production of laser diodes with several heterojunctions between GaAs and (GaAl)As, the individual layers having different Al contents. For N-doped and ZnO-doped GaP diodes that radiate in the visible region, LPE is the usual method if maximum efficiency is a prime concern.

Because of its simpler handling and greater versatility with respect to specific compositions, *vapor-phase epitaxy* (*VPE*) is being used increasingly for mixed crystals, especially if components with high vapor pressure are involved. However, VPE makes considerable demands in terms of equipment sealing and purity of the gases used where the metal components, e.g., Al, are highly sensitive to oxygen. Vapor-phase epitaxy is also used for the manufacture of Ga(As, P) LEDs, since the As : P ratio in the growing layer can be regulated via the AsH_3 and PH_3 concentration in the gas phase.

Gallium is introduced by reacting liquid gallium with HCl at high temperature, which preferentially produces GaCl. On the substrate crystal, which is at low temperature, GaCl disproportionates to Ga and $GaCl_3$. On the substrate the resulting gallium combines with the arsenic and phosphorus molecules (As_n and P_n) present in the gas. Instead, $AsCl_3$ and PCl_3 can be reacted with gallium to provide GaCl, As_n, and P_n. Gaseous dopants such as H_2S, H_2Se, and H_2Te are suitable for producing *n*-type conduction; zinc or an organozinc compound produces *p*-type conduction. Nitrogen is introduced as an active isoelectronic center by means of NH_3. Frequently, however, *n*-type layers produced by VPE are converted to a *p-n* junction by diffusion treatment in zinc vapor or by introduction of zinc ions by ion implantation and subsequent annealing. Both processes can be carried out either across the whole area or locally by means of a window etched into an SiO_2 cover layer similar to the planar technology processes used in microelectronics.

In VPE, increasing use is being made of gases to transport the metal components. Organometallic compounds such as trimethyl- or triethylgallium and the analogous aluminum or indium compounds are especially suitable for this purpose. The designation VPE then becomes *MOVPE.*

Since optoelectronic integrated circuits and integrated optics require, in the limiting case, atomically smooth and thin layers and layer sequences (superlattice structures), a new technology was developed for their production. *Molecular beam epitaxy* (*MBE*) or *organometallic molecular beam epitaxy* (*MOMBE*) operates at ultrahigh vacuum (UHV) with Knudsen evaporators, which can be adjusted extremely accurately, and liquid or gaseous compounds of the components, e.g., metal alkyls, as the material source. Local doping can be implemented by ion implantation or, for fine structures, ion lithography. The necessary equipment can be integrated directly into the UHV unit. In this way, a fully automated UHV technology is available for the most advanced electroluminescence components.

4. Practical Luminescent Diodes

4.1. Diodes Producing Red, Yellow, and Green

The main use for luminescent diodes is emission of visible light. Here they have replaced earlier incandescent filaments and gas discharge lamps, attaining good color contrast and intensities adapted to eye sensitivity. Systems emitting red, yellow-orange, and green light have been selected for practical applications. Red diodes (Table 3) consist of $GaAs_{0.6}P_{0.4}$ on opaque GaAs or, better still, N-doped $GaAs_{0.35}P_{0.65}$ on a transparent GaP substrate. Yellow-orange is obtained optimally with $GaAs_{0.15}P_{0.85}$ and green with GaP, both on GaP substrate and N-doped. Table 2 also lists the color and the best light yield, i.e., the number of lumen for every watt of input power, for the most important materials. The values for commercial luminous diodes are around 0.2 lm/W for GaAs substrate; however, for GaP substrate they are better than 0.5 lm/W.

After the epitaxial layers have been produced, contact metals are vaporized onto the crystals: an Au or Ag alloy containing Sn, Si, or Ge for the *n* side, and an Au or Ag layer containing Zn, Be, or Mg for the *p* contact. After the crystal has been split by diamond cleavage – splitting along (110) crystal faces – or by sawing with diamond-impregnated rotary disks or wire saws, the diode systems are alloyed onto a conductive band or glued with a conductive adhesive. Gold wire is used for the electrical connection on the upper side.

The diode is subsequently encapsulated with a plastic that has two main functions: (1) to protect the system against mechanical damage, and (2) to gradually adapt the refractive index to air, which increases the external light yield.

Table 3. Direct semiconductor materials for commercial red and infrared light emitting diodes: band-to-band transitions

Crystal system	Emission wavelength, μm	Luminous efficacy, lm/W	Efficiency∗, %
Red light emitting			
GaAsP on GaAs substrate	0.66	0.4	
GaAlAs on GaAs substrate	0.65	5.0	
GaAlAs on GaAlAs substrate	0.65	15.0	
Infrared emitting			
GaAs : Si	0.94		6
GaAs : Zn	0.91		1
GaAlAs	0.88		12
	0.82		2
GaInAsP	1.30		0.5
GaAsP	0.70		0.5

∗ Photons emitted per injected current carrier (electron).

The semiconductor crystal itself has a refractive index n of 3 – 4, and without plastic encapsulation a large part of the light generated would be lost because of total internal reflection.

Special shaping of the plastic surface improves the focusing of the emitted light, and finely dispersed light-scattering particles of SiO_2 or TiO_2 in the plastic produce a uniformly luminescent surface. In addition, this plastic can be tinted to improve the contrast and change the color. For example, N-doped GaP diode systems that have a natural yellow-to-green emission can be made into yellow or green diodes. However, there is an accompanying loss in efficiency.

4.2. Blue Light Diodes

The indirect semiconductor silicon carbide, which has a bandgap of 2.98 eV for the polytype 6H, is of practical importance for blue light-emitting diodes. This material may be produced in n- and p-conducting forms by doping, which distinguishes it from other materials, such as GaN, ZnS, or ZnSe, that might be used for emission in the blue region of the spectrum. The effective photoemission mechanisms have not been fully explained. Transitions between the conductance and valence bands, possibly including transitions via donors and acceptors (e.g., N – Al pairs emitting at 0.5 μm) have been proposed as possible mechanisms. The optical yield of these devices is small, with an external efficiency <0.01 %. However, SiC has a high current carrying capacity, making high luminescence values attainable.

Blue-light diodes of this kind are not yet available commercially. Their production involves considerable difficulties, since large SiC crystals must be used as the substrate for the doped p-n layer sequences, which are manufactured by liquid-phase epitaxy.

The requisite crystals and p-n layer sequences must be crystallized out from silicon melts containing carbon and dopants (Al, N) above 1800 °C. The problems associated with this technology have been solved, but this high-temperature method proceeds slowly and is costly. For the time being blue-light diodes can be introduced only for special applications.

4.3. Infrared Diodes

For some applications, e.g., optical communications and light barriers, GaAs diodes emitting between 0.8 and 1.1 μm are used (see Table 3). Since high output power is often important, the high refractive index and the self-absorption of these devices call for special measures. All light that strikes the boundary with an angle of reflection greater than that of total reflection returns to the crystal interior and is lost by self-absorption. A hemispherical diode surface provides a good solution, allowing an output power exceeding 1 W at 30 % efficiency. Since optical paths in the crystal are quite long, the absorption must be reduced by shifting the absorption edge to shorter wavelength by high n-doping and by red-shifting the light emission by simultaneous high p-doping using amphoteric silicon or a combination of donors and acceptors as dopants.

4.4. Optoelectronic Couplers

If the light is required only for electrical decoupling within an electrical circuit or for simple coupling of optoelectronic circuits, an emission diode and a receiver (photodiode or transistor) can be connected via a highly refractive medium having high insulation strength and long-term stability, to produce a practical coupling device.

Apart from plastics with a refractive index of 1.4 – 1.8, semiconductive glasses, e.g., the (As, S, I) and (Ge, P, Se) compounds with refractive

indexes up to 2.4 (→ Glass) are candidates to connect the emitter with the detector.

5. The Laser Diode as a Source of Coherent Light

Laser diodes can be realized with various semiconductors. Lasing can be recognized by the rapid increase in emission accompanied by a decrease in line width when a specific threshold current, corresponding to a current density of ca. 1 kA/cm^2, is exceeded.

The active volume, i.e., the layer excited by carrier injection, is limited by two adjacent layers with somewhat higher aluminum content, and thus greater bandgaps, which reduce the threshold current density. Since the refractive index also drops at both inner junctions, the emitted light is not deflected into these regions, and wave conduction occurs in the active layer. This reduces the optical losses and reduces the threshold current density even more. The threshold current is reduced in absolute terms even further by a reduction of the width of the excited area of the diode and by extremely effective heat dissipation (e.g., by diamond). This stripe geometry also allows monomode operation, i.e., only a single oscillation mode is excited in the diode. Since most of the generated light is available at the front windows, the diode has high external efficiency, up to 50 %, and high radiation densities, $10^4 - 10^6$ W/cm^2. The maximum operating temperature increases as the threshold current is decreased.

Figure 4 schematically represents the four most important structures involving GaAs lasers (emission at ca. 850 µm) [17]: the oxide stripe laser, the metal-clad ridge waveguide (MCRW), the buried heterostructure (BH) laser, and a planar buried ridge structure (PBRS) laser with a distributed feedback (DFB) lattice structure. The first three are Fabry-Perot resonators, while the last is a grating resonator. In the oxide stripe laser, the current is confined by a window stripe in an insulating oxide cover layer. In the MCRW laser, the thickness of the light-emitting layer is limited by two heterojunctions. The area of the active layer is determined by the width of a narrow ridge, which simultaneously confines lateral current flow and the propagating optical wave. In addition, the active area of the buried heterostructure (BH) laser is limited by two vertical heterojunctions provided by the burying layer. In the DFB laser, a buried heterostructure, the active region, is confined vertically and horizontally, like the BH laser. The grating serves for feedback of radiation along the resonator axis and provides for stable single-mode operation. In all these cases, to allow steady operation at room temperature, the operating current must be kept as small as possible, and heat dissipation must be good. Available power and emission wavelength are the most important parameters for laser-induced chemistry, whereas narrow line width is important for chemical analysis.

Table 4 lists operating data for the laser structures in Figure 4 as well as for high-power arrays. Particularly interesting is the monolithic

integrated laser diode array produced from many (40 in this case) parallel stripe lasers with a spacing of about 0.01 mm, as shown in Figure 5. It is a GaAs power laser with a total output power for both mirrors of 3 W and a permissible constant operating current of 5 A at 300 K (Fig. 6).

Uses. Laser diode devices are used in optical communications for local-area networks and in wideband communications (integrated services digital network, ISDN). Long distances, over 100 km without repeaters, and high data rate, exceeding 1 Gbit/s, have been realized. In computer technology, power lasers are used to write or read information on optical memories, the most important example being the digital compact disk (CD), while applications for video systems and large memories (100 Gbyte) are in the offing. Even more powerful arrays will be required for laser printing, material machining, and microsurgery. Laser diodes provide more efficient resonant pumping for solid-state lasers, an efficiency increase by a factor of 10^3. Laser chemistry, i.e., the induction of specific chemical reactions, should extend the applications of semiconductor lasers significantly. The 1985 sales figure for laser-linked products, \$ 3.5×10^9 (€ 3.3×10^9), is expected to grow by 50 % per year.

1. Introduction

The chemicals and materials used to manufacture and package semiconductors and printed circuit boards are considered electronic chemicals. The more than 100 different products used in these applications are grouped into the following 13 major product categories:

acids and etchants (Chap. 6)
atmospheric gases (Chap. 7)
auxiliary materials (Chap. 14)
cleaners (Chap. 9)
dopants (Chap. 13)
masks (Chap. 12)
packaging materials (Chap. 3)
photoresists (Chap. 5)
photoresist adjuncts (Chap. 8)
plating chemicals (Chap. 4)
solvents (Chap. 11)
specialty gases (Chap. 10)

substrates (Chap. 2)

Semiconductors are devices having a specific electronic circuit fabricated onto a single square or rectangular piece of semiconducting material such as silicon (→ Semiconductors). The two main types of semiconductor devices are *discrete devices* and *integrated circuits* (IC). Discrete devices contain only one active element, whereas integrated circuits contain multiple elements that act together to form a complete electronic circuit. Since the semiconductor industry began in 1947 with the invention of the transistor and was further enhanced by the invention of the integrated circuit in 1958, the business has grown rapidly.

More than 100 manufacturers of semiconductor devices exist in the United States, including both merchant and captive producers. International Business Machines (IBM), a captive producer, is believed to be the largest semiconductor manufacturer worldwide. Other important semiconductor manufacturers include Texas Instruments, Motorola, National Semiconductor, Intel, Fairchild, Signetics, AT & T, and Advanced Micro Devices in the United States; Philips (Netherlands); Siemens (Federal Republic of Germany); and NEC, Hitachi, Toshiba, and Fujitsu (Japan).

Printed circuit boards are plastic sheets onto which conductive paths are formed in a specific pattern for the purpose of interconnecting electronic components such as semiconductor devices, resistors, and capacitors. The circuitry can be formed on either one side or both sides of the board, and several boards can be connected to produce a multilayer board. The need for printed circuit boards is widespread, and they are either produced captively by large consumers or purchased on the merchant market.

Of the over 1000 individual manufacturers of printed circuit boards in the United States, two companies, IBM and Western Electric, are by far the largest producers. Other important manufacturers include Hewlett-Packard, Digital Equipment, Delco, Tyco Laboratories, Hadco, and Photocircuits (United States); GEC (United Kingdom); Telefunken (Federal Republic of Germany); Olivetti (Italy); Thompson-CSF (France); and NEC, Hitachi Chemical, CMK, and Fujitsu (Japan) [4].

2. Substrates

A substrate is the base material in the manufacture of semiconductor devices and printed circuit boards. The semiconductor industry uses materials, such as silicon and gallium arsenide, which are produced in single crystal form. Thin circular slices or wafers of these single crystal materials serve as the substrate in manufacturing semiconductor devices.

The printed circuit board industry uses materials known as laminates to act as the base in the production of circuit boards. Combinations of a resin with either paper or glass cloth form the laminate, which is produced in thin sheets.

2.1. Silicon Wafers

Types and Grades. Silicon [*7440-21-3*] wafers are sold as either polished wafers or epitaxial wafers, i.e., wafers having an added silicon layer over the surface, that has the same crystallographic orientation as the wafer itself. All wafers are manufactured with dopants embedded in the silicon. Wafers positively doped with boron or negatively doped with either antimony or phosphorus are available. Silicon wafers are also sold in two types of crystal lattices: (100) and (111) orientations.

Production. The two major methods of producing silicon wafers are the Czochralski method and the Floating Zone technique (→ Crystal Growth).

The *Czochralski method* is the most widely used crystal growing process. Pure polycrystalline silicon is placed in a fused silica quartz crucible. The material is heated to 1400 °C in a protective atmosphere, usually argon, which melts the silicon and keeps it molten. A seed crystal of the desired crystal orientation is dipped into the melt. The single silicon crystal is grown by rotating the seed and the crucible in opposite directions while withdrawing the seed.

The *Floating Zone technique* uses a rod of polycrystalline silicon attached to a chuck at the top of an inert atmosphere chamber and a seed crystal attached to a shaft at the bottom of the chamber. A heating coil located at the base of the

rod forms a molten zone, which is fused with the seed to begin crystal growth. Movement through the molten zone purifies the polysilicon and establishes the crystal structure. The molten silicon is kept in place by surface tension, which limits the diameter of the pure silicon.

The major drawback of the Floating Zone method in comparison to the Czochralski process is the limited wafer diameter. The Floating Zone process can produce a maximum wafer diameter of 7.6 cm, whereas wafer diameters up to 15.2 cm are feasible with the Czochralski method. Both processes add controlled amounts of impurities or dopants during the growth process to create the necessary electrical properties within the silicon crystal structure. Dopants, such as boron, are added to establish a positive charge within the silicon; phosphorus and antimony are used to create a negatively charged material. In the Czochralski process, dopants are typically added to the molten silicon as pure elements or concentrated silicon solutions. The Floating Zone method uses dilute phosphine or diborane gas, which is added when the rod is in the molten zone or when the rod is initially manufactured.

Quality Specifications. The dimension and thickness specifications for polished silicon wafers have been established by the Semiconductor Equipment and Materials Institute (SEMI) [5].

Uses. Silicon is used as a substrate for discrete semiconductor devices, such as diodes, rectifiers, and transistors, as well as for all types of integrated circuits (IC). Wafers produced by the Czochralski process are used primarily for ICs and transistors, whereas those manufactured by the Floating Zone method are used mainly for rectifiers and thyristors.

Economic Aspects. The consumption of silicon wafers in the United States was ca. $3\times10^9\,cm^2$ in 1980. The demand in Western Europe during the same period was 0.742 $\times10^9\,cm^2$. The leading suppliers worldwide of silicon wafers are Wacker (Federal Republic of Germany), Monsanto (United States), Shin-Etsu Handotai (Japan), and Dynamit Nobel (Italy).

2.2. Other Semiconductor Substrates

Gallium arsenide [*1303-00-0*], GaAs, is a substrate produced by the Czochralski process from a molten mix of gallium and arsenic metals. It is sold as wafers, with diameters of 5.08 and 7.62 cm being the most popular. Most GaAs is used as the base material for light-emitting diodes, although it does have applications with other discrete devices, such as field-effect transistors, Gunn diodes, and Schottky diodes. Gallium arsenide is also an electrically fast substrate material and is of interest as a potential source for producing very-high-speed integrated circuits.

Some of the more important suppliers of gallium arsenide include Sumitomo Electric Industries and Mitsubishi Monsanto (Japan), Morgan Semiconductor (United States), and Wacker (Federal Republic of Germany).

Silicon-on-sapphire (SOS) is produced by epitaxially depositing a thin silicon layer on a sapphire substrate. It is sold as wafers, with the 7.62 cm diameter variety being the most common. As a substrate material, SOS is capable of producing dense, high-speed devices that are resistant to radiation. However, its manufacture is both difficult and expensive. Despite attempts to develop SOS for commodity type devices, it remains mainly as a material for specialty devices in military applications.

The United States is the main market for SOS substrates as a result of its military applications. Union Carbide and Sappikon are the major U.S. suppliers of SOS substrates. Small quantities of SOS are used in Japan mainly by Toshiba, which supplies some of its internal requirements.

Gadolinium gallium garnet (GGG) [*12024-36-1*], $Gd_3Ga_5O_{12}$, is manufactured from gadolinium oxide and gallium oxide by the Czochralski method. Single-crystal GGG is available in wafer form with a typical diameter of 7.62 cm and thicknesses of 5 – 6 µm. The main application for GGG is as the substrate material for magnetic bubble memories, a relatively new device that can store $>10^6$ bits of information. Gadolinium gallium garnet (GGG) is electrically involatile; however, it is a relatively slow electrical semiconductor. Unfortunately, the de-

mand for magnetic bubble memories has been limited.

2.3. Printed Circuit Board Laminates

Laminates are used as the substrate for printing electrical circuitry. They are composed of layers of material compressed under heat and pressure to form a consistent electrical insulator. The basic raw materials of the laminate include paper and glass cloth, or glass mat bonded with one of several resins, mainly phenolic, epoxy, or polyester. Circuit boards processed by the substractive method use laminates clad with copper foil, whereas the additive and semiadditive methods use unclad laminates,

Types and Grades. Laminates are manufactured specifically for circuit printing on both sides (double-sided board) or an only one side (single-sided board) and can be either rigid or flexible in form. The types of laminates available commercially are given in Table 1 [6].

Uses. Paper-based phenolic and composite laminates are used as substrates for single-sided and simple double-sided circuit boards. These boards are typically used for less critical consumer items, such as electronic games, televisions, appliances, calculators, and automotive circuits. Glass-based epoxy and polyimide laminates are favored for complex double-sided and multilayer boards that have applications with computers, communication equipment, and other electronic devices requiring a high degree of reliability.

Economic Aspects. Total demand for printed circuit board laminates in the United States was $20\times10^6\,m^2$ in 1980. The demand in Western Europe was $15\times10^6\,m^2$ during the same period. The major laminate suppliers include Norplex and Oak Laminates (both of which are part of Allied-Signal), Westinghouse, and General Electric (United States); Dynamit Nobel and Isola (Federal Republic of Germany); MAS (Italy); and Hitachi Chemical, Sumitomo Bakelite, and Matsushita Electric (Japan).

3. Packaging Materials

3.1. Ceramic Packaging Materials

Ceramic materials are used to encase semiconductor devices to protect the devices from the adverse effects of moisture, atmospheric salt, and high temperature (→ Ceramics, Electronic). Because ceramic packages provide a high degree of hermaticity and reliability, ceramics are generally used to package critical military, computer, and communication devices.

Most ceramics used in packaging are made from aluminum oxide [*1344-28-1*], Al_2O_3, although beryllium oxide [*1304-56-9*], BeO, is sometimes used. Aluminum oxide is very strong and refractory and has a low dielectric constant, which makes it suitable for most packaging applications. Beryllium oxide offers the unusual combination of high thermal and electric conductivity. However, the high cost of this material limits its use to the most critical applications.

Types and Grades. Most ceramic packages contain 94 wt % aluminum oxide, although other compositions are available. The major types of ceramic packages are (1) the metallized ceramic dual in-line package (DIP), (2) the ceramic dual in-line package (CERDIP), and (3) the chip carrier. Other types include specialty beryllium oxide packages.

Uses. The type of ceramic package used with a semiconductor device depends on (1) the level of hermetic seal desired, (2) the degree of reliability required, (3) the amount of space alloted to the device on the printed circuit board, and (4) the total package cost. A ceramic package that is metallized by cofiring the alumina powder with tungsten forms the tightest hermetic seal of all types of packages, whether ceramic or plastic. However, this package is also the most expensive, except for the seldom used beryllium oxide-type package. Because of their high reliability, DIPs are most often used for devices used by the military and for the more critical devices used in computers and communication equipment.

The *CERDIP,* which has no metallization, offers a compromise between the level of hermetic seal and package cost. As a result, the CERDIP is favored for many computer and communication applications where a more hermetic seal is

Table 1. Standard laminate materials

NEMA grade	MIL-P-13949E∗	Resin system	Base	Color	Description
XXXP	none	phenolic	paper	opaque brown	phenolic paper with no cold-punch stipulation
XXXPC	none	phenolic	paper	opaque brown	phenolic paper with punchability at or above room temperature
FR-2	none	phenolic	paper	opaque brown	phenolic paper, punchable, with flame-resistant (self-extinguishing) resin system
FR-3	PX	epoxy	paper	opaque cream	epoxy resin, paper base with flame-resistant resin system, cold punching, and high insulation resistance
none	none	epoxy	paper – glass composite	opaque cream	epoxy resin paper core with glass on the laminate surface, self-extinguishing, economical fabrication of paper base, mechanical characteristics of glass
FR-6	none	polyester	glass mat	opaque white	polyester, random glass fiber, flame-resistant, designed for low-capacitance or high-impact applications
G-10	GE	epoxy	glass	translucent green or white	epoxy – glass, general purpose
FR-4	GF	epoxy	glass	translucent green or white	epoxy – glass with self-extinguishing resin system
G-11	GP	epoxy	glass	translucent green or white	high-temperature epoxy – glass with strength and electrical rentention at elevated temperature
FR-5	GH	epoxy	glass	translucent green or white	high-temperature epoxy – glass with flame-resistant resin system; strength and electrical retention at elevated temperature
		polyimide	glass	translucent dark brown	polyimide resin, glass laminate with high continuous operating temperature and high property retention at high temperature, low z-axis dimensional expansion

∗ Military designation.

desired than plastic can be obtained using a package, but where cost limitations prevent use of a DIP.

The *chip carrier* was developed to fulfill the needs of systems manufacturers for (1) increased package density, (2) better electrical performance, and (3) more economical device packaging. It has a metallized aluminum oxide ceramic substrate similar to that of a DIP. Its shape is square, whereas both the DIP and CERDIP are rectangular. The square configuration of the chip carrier reduces the space requirements on a printed circuit board by 3 – 5 times compared to that of the DIP and CERDIP. The square shape also improves electrical performance by shortening the length of the electrical leads and by making the lead length more uniform over the entire package, thus permitting faster switching times and improved system performance. Overall, the chip carrier produces a hermetic seal nearly as tight as that of the DIP, but at < 50 % the cost.

Economic Aspects. In 1980, ca. 2.2×10^9 ceramic packages were used in the United States for packaging semiconductor devices. At the same time, ca. 87×10^6 ceramic packages were consumed. The two leading suppliers of ceramic packages are Kyocera and NTK Technical Ceramics, both Japanese companies.

3.2. Plastic Packaging Materials

Plastic packaging materials are used to encase the finished semiconductor device, thus protecting the device from moisture, atmospheric salt, and high temperature. The four basic types of plastic materials used for this purpose are as follows:

Epoxy molding resins are used primarily to package metal oxide semiconductor (MOS) and bipolar devices that require an inexpensive package while still receiving protection from the environment (→ Epoxy Resins). Epoxy resins offer low shrinkage and high strength, which help to prevent package cracking both on curing and from the thermal shock.

Silicone molding resins are favored for packaging devices, such as power transistors, which generate a great amount of heat. Silicone resins are among the best of all polymeric materials for operating at high temperature. They also have excellent electrical properties, which change little with temperature.

Silicone-epoxy resins are hybrids that attempt to combine the best qualities of each resin while maintaining a low package cost. So far, these resins have been used with some telecommunication devices that seek a better hermetic seal than that from epoxy resins while maintaining a package cost close to that of epoxy.

Liquid potting compounds are generally used to package discrete devices such as transistors and diodes. These potting compounds offer the lowest package cost, but also the least amount of protection from the environment.

Types and Grades. Plastic packaging materials are all sold as semiconductor-grade products. The molding resins are available in granular form, whereas potting compounds are sold as liquids. All products are marketed in ready-to-use form.

Uses. Two main processes are used for packaging semiconductor devices.

Transfer molding is the process of transferring a hardenable material, under pressure, from a pot or container into the mold that contains the semiconductor device. This process is economical for large-volume operations, but initial facility construction and mold costs are high. All molding resins use this process for packaging devices.

Potting consists of pouring a hardenable liquid into a shell or housing, which remains as an integral part of the package. This process is also excellent for large-volume runs and requires minimal tooling. However, this process is subject to limitations of both size and housing complexity. Liquid potting compounds are used exclusively in this packaging process.

Economic Aspects. Worldwide consumption of plastic packaging materials in 1980 is shown in Table 2. Epoxy-based molding compounds were the preferred product.

Table 2. Worldwide consumption of plastic packaging materials in 1980

Product	Consumption, 10^3 t		
	United States	Western Europe	Total
Epoxy	10.0	1.4	11.4
Silicone	1.1	0.2	1.3
Liquid potting	0.6		0.6
Silicone – epoxy	0.2		0.2
Total	11.9	1.6	13.5

The major suppliers of epoxy molding compounds are Rohm & Haas and the Hysol Division of Dexter, both in the United States. Dow Corning (United States) is one of the most important suppliers of silicone molding compounds.

4. Plating Chemicals

4.1. Electrolytic Gold Plating Chemicals

Gold [*7440-57-5*] plating on printed circuit boards functions mainly as the surface metal for contact areas because of its high electrical conductivity and resistance to tarnish. Gold can also function as a metal etch resist because of its resistance to all common circuit board etchants. Electrolytic gold plating chemicals consist of gold salts, gold strikes, conductivity salts, and pH-adjusting salts.

Gold salts, also known as gold plating processes, are proprietary formulations of either potassium gold cyanide or alkaline noncyanide gold in either powder or solution form. In addition to supplying gold metal for plating, these formulations often include brighteners to produce a mirror finish or complexes of cobalt, nickel, and indium for increased hardness and wear resistance.

Gold strikes are used to deposit a thin layer of gold on other plated metals prior to the use of a noncyanide gold plating solution or an electroless gold plating process. The thin gold layer

improves the bonding of the noncyanide or electroless gold layers to the circuit board.

Conductivity salts allow gold plating baths to operate at a lower voltage, thus increasing bath efficiency; *pH-adjusting salts* are used to raise or lower the pH of the bath.

Production. All electrolytic gold baths and strikes are prepared by mixing the conductivity salts in water and adding either the gold salt or gold strike to the solution. Some pH-adjusting salts may be added initially to obtain the proper pH. Once the bath is operating, only gold salts (and occasionally some pH-adjusting salts) are added to replenish the bath. Gold baths are long lasting and are reformulated only once or twice per year. Acid gold baths operate at a temperature of 21 – 49 °C with a pH of 3.5 – 4.0, whereas alkaline noncyanide gold baths operate at 32 – 54 °C with a pH of 9.0 – 10.0 [7].

Types and Grades. Gold salts are available in three types and four grades (see Table 3), as defined by the U.S. Department of Defense specification MIL-G-45204 B Amendment 2 for electrodeposited gold plating [7, p. 28]. The type of gold salt refers to the purity of the gold deposit, whereas the grade refers to the hardness of the deposit as measured by the Knoop method.

Table 3. Types and grades of gold salts

Type	Gold purity (min.), wt %	Grade	Knoop hardness
I	99.7	A	0 – 90
II	99.0	B	91 – 129
III	99.9	C	130 – 200
		D	≧ 201

Gold concentration in the salts varies with vendors, but most salts have concentrations of ca. 67 %.

Uses. Electrolytic gold plating is used on printed circuit boards for end uses such as computers, communications, and the military, all of which require a high degree of reliability. The thickness of plated gold varies among printed circuit board manufacturers. Western Electric has developed a specification requiring a plated gold thickness of 1.27 µm. Specifications for other communication and computer companies range from 0.762 to 2.03 µm and military requirements can typically vary from 2.54 to 3.81 µm.

Economic Aspects. An estimated 5.3 kg of gold metal and formulation chemicals was consumed in the United States for electrolytic gold plating on printed circuit boards. The major suppliers of gold plating processes are Oxy Metal Industries, Engelhard, and Lea Ronal, all in the United States.

4.2. Electroless Copper Plating Chemicals

Electroless plating is used to deposit thin metal layers on nonmetallic surfaces without the use of an electric current. Most electroless plating is used for depositing copper [*7440-50-8*], which functions to metallize nonconductive surfaces on printed circuit boards. Electroless copper plating systems consist of a solution, a catalyst, and an accelerator.

Electroless copper solutions are usually a proprietary two-component system. One component contains copper(II) salts and formaldehyde, whereas the other contains sodium hydroxide. When these solutions are combined in water, copper is reduced as follows [7]:

$$2\,Cu^{2+} + HCHO + 3\,OH^- \xrightarrow{Pd} 2\,Cu^+ + HCOO^- + 2\,H_2O$$
$$2\,Cu^+ \rightarrow Cu^0 + Cu^{2+}$$

Electroless copper catalysts are proprietary formulations containing both palladium chloride and tin(II) chloride. The palladium is essential for initiating the copper reduction reaction on a nonconductive surface. Once copper is deposited, the reaction is autocatalytic.

Electroless copper activators are proprietary formulations that increase the ability of the palladium catalyst to reduce copper more rapidly and uniformly. The activator also improves adhesion of the electroless copper to the base metal.

Production. All electroless or immersion plating is conducted by submerging the circuit board into a prepared bath. Most electroless copper baths operate at a temperature of 21 – 27 °C with a pH of ca. 12 [7, p. 6]. The difference between electroless solutions and immersion solu-

tions is subtle but important. Electroless solutions contain a reducing agent that supplies electrons to reduce metal ions to the metallic state. Theoretically, an electroless bath can proceed indefinitely. Immersion plating is accomplished by displacing one metal with another of lower oxidation potential. As a result, plating ceases when all the metal on a given substrate has been displaced.

Types and Grades. All electroless copper plating chemicals are sold as a concentrate that requires dilution with water before it is ready for use. Many suppliers have different dilution rates for the various electroless chemicals because of the wide range of concentrations available.

Uses. Electroless copper plating is used to deposit metal on the nonconductive walls of holes that are drilled in double-sided and multilayer boards. The metallized holes allow the printed circuitry to connect both sides of a board. Other electroless plating systems are employed only occasionally for specific functions. Electroless nickel solutions and immersion tin or tin – lead solutions can be used to inhibit corrosion and promote solderability on a completed circuit board. Electroless or immersion gold solutions are used when electroplating is impractical because of a lack of electrical continuity on the edge connectors.

Economic Aspects. In 1980, ca. 6.1×10^6 L of electroless copper plating chemicals was used in the United States; half that amount was consumed in Western Europe. MacDermid and Shipley both in the United States, are the two major suppliers of these plating chemicals.

4.3. Electrolytic Copper Plating Chemicals

Electrolytic copper plating chemicals are used to deposit copper onto printed circuit boards. Copper is widely accepted as a base conductor metal in circuit board fabrication because of its excellent electrical conductivity, low cost, high reliability, and good bonding with other metals. The two most commonly used copper processes are acid sulfate and pyrophosphate. The chemicals used in the *acid sulfate process* are copper sulfate, sulfuric acid, copper anodes, and proprietary brighteners, whereas the *pyrophosphate process* uses copper pyrophosphate, potassium pyrophosphate, copper anodes, and proprietary additives.

Copper(II) sulfate [*7758-98-7*], $CuSO_4$, is the source for copper ions, which are plated onto the board in an acidic copper bath. A chemically pure grade copper sulfate is usually recommended for plating.

The function of *sulfuric acid* [*7664-93-9*], H_2SO_4, is to increase the conductivity of the bath solution and to corrode the copper anodes. *Copper* serves as the anode for the electrical current and supplies copper to form copper sulfate as corrosion takes place in acid baths. Acid copper baths require phosphorized anodes, whereas oxygen-free high conductivity or rolled phosphorized anodes are used in pyrophosphate baths.

Copper and potassium pyrophosphate [*7320-34-5*], $K_4P_2O_7$, are combined to form potassium copper pyrophosphate, which serves as the source of copper ions in a pyrophosphate bath. *Proprietary brighteners* are added to the bath to increase grain refinement, hardness, distribution, and brightness of the plated copper. These additives are used to a much greater extent with acid copper systems than with pyrophosphate systems.

Types and Grades. Copper sulfate is available in both technical and chemically pure grades for use in electroplating and can be purchased as a commodity or as a trade name in either liquid or crystalline form. Copper sulfate is also sold in a dilute form mixed with sulfuric acid and water for a ready-to-use bath solution. Copper anodes are sold either as chips or rods. Pyrophosphates are available as both solutions and crystals and are usually bought as a trade name product. Proprietary brighteners are sold as ready-to-use liquid concentrates.

Uses. Both the acid copper and pyrophosphate processes are used to deposit copper on the printed circuit board to form the circuitry. The thickness of the plated copper varies among circuit board manufacturers, but the typical range is 2.54 – 5.08 μm, regardless of the plating process. Acid copper operates at a temperature of 18 – 32 °C, whereas pyrophosphate

operates at 43 – 60 °C and requires a pH of 8.2 – 8.8. Typical bath compositions for acid copper and copper pyrophosphate are as follows [7, pp. 14, 16]:

Acid copper bath	
Copper(II) sulfate	25 vol %
Sulfuric acid	10 vol %
Chloride ion	50 ppm
Brightener	0.6 vol %
Deionized water	74.4 vol %
Copper pyrophosphate bath	
Copper(II) pyrophosphate	33.3 vol %
Potassium pyrophosphate	3.5 vol %
Ammonium hydroxide	0.5 vol %
Brightener	0.09 vol %
Deionized water	62.6 vol %

Economic Aspects. In the United States, ca. 4.8×10^3 t of copper anodes and 5.7×10^3 m^3 of copper plating chemicals were consumed for electrolytic copper plating in 1980. The major suppliers of the plating chemicals are Sel-Rex and Lea Ronal in the United States. Copper anodes are available from many suppliers, with such companies as AMAX, ASARCO, and Univertical among the more important.

4.4. Electrolytic Tin – Lead Plating Chemicals

Tin – lead or solder is electroplated onto the printed circuit board by using electrolytic tin – lead plating chemicals. The plated solder serves two functions: as a metal etch resist for the copper circuitry and as a solderable substrate for subsequent soldering of components to the board. Tin – lead plating baths consist of anodes, lead and tin tetrafluoroborates, fluoroboric acid, boric acid, and brighteners. Fluoroboric and boric acid are discussed further in Chapter 6.

Lead (II) tetrafluoroborate [*13814-96-5*], $Pb(BF_4)_2$, and *tin(II) tetrafluoroborate* [*13814-97-6*], $Sn(BF_4)_2$, are the sources of metal for deposition onto the board. Variations in the metal content of the bath can affect the content of the deposition alloy.

Fluoroboric acid [*16872-11-0*], HBF_4, increases bath conductivity and corrodes the tin – lead anodes. *Tin – lead* (Sn [*7440-31-5*], Pb [*7439-92-1*]) serves as the anode for the electrical current and supplies tin and lead to form $Sn(BF_4)_2$ and $Pb(BF_4)_2$ as corrosion takes place.

Boric acid [*10043-35-3*], H_3BO_3, is added to maintain bath stability by inhibiting the decomposition of tetrafluoroborate. Two types of *brighteners* are available: peptones and nonpeptone proprietary brighteners promote smooth, fine-grain deposits.

Types and Grades. Lead and tin tetrafluoroborates are available as liquid concentrates with 50 % active material content, usually of a chemically pure grade. Tin – lead anodes are sold in both rod and nugget form with a minimal purity of 99.9 %. Brighteners are sold as ready-to-use liquid concentrates.

Uses. Solder plating is typically used on double-sided boards and outer layers of multilayer boards. Solder is plated on top of the electroplated copper to serve mainly as an etch resist for the copper. The thickness of most tin – lead deposits is 7.62 – 12.7 µm. Tin – lead baths usually operate at a temperature of 21 – 27 °C [7, p. 21].

Economic Aspects. In 1980, ca. 1.4×10^3 m^3 of tetrafluoroborates, acids, and brighteners was consumed in the United States for electrolytic tin – lead plating in electronics, along with 1.1×10^3 t of tin – lead anodes. The more important suppliers of the plating chemicals are General Chemical (formerly Allied), Sel-Rex, Lea Ronal, and Harshaw. By far, the most important supplier of tin – lead anodes is Alpha Metals.

4.5. Other Electrolytic Plating Chemicals

Several other electrolytic plating processes are employed by the printed circuit board industry. Among the most important processes are nickel, tin, and rhodium plating.

Nickel electroplating uses such products as nickel sulfamate or nickel sulfate, boric acid, nickel bromide, nickel anodes, and proprietary additives. *Nickel sulfamate* [*13770-89-3*], $Ni(SO_3NH_2)_2$, is the primary source of nickel metal ions in a nickel sulfamate bath, whereas

nickel sulfate [*15244-37-8*], $NiSO_4$, serves the same function in a modified watts nickel bath. *Boric acid* functions as a buffer and reduces burning at high current densities. *Nickel bromide* [*13462-88-9*], $NiBr_2$, is used to minimize internal stress and cause corrosion of the nickel anodes. *Nickel* [*7440-02-0*] serves as the anode for the electric current and provides additional nickel ions as corrosion takes place. *Proprietary additives* are used to reduce stress and impart a semibright appearance to the deposit.

Tin electroplating requires the use of tin sulfate, sulfuric acid, tin anodes, and proprietary brighteners. *Tin(II)* sulfate [*7488-55-3*], $SnSO_4$, acts as the source of tin ions. *Sulfuric acid* increases bath conductivity, solubilizes the tin salts, and corrodes the tin anodes. *Tin* [*7440-31-5*] supplies additional tin ions through corrosion and functions as the anode for the electric current. *Proprietary brighteners* serve to brighten and level the distribution of the deposit.

Rhodium electroplating uses proprietary rhodium salt solutions, sulfuric acid, and platinized titanium anodes. The *proprietary rhodium solutions* supply the metallic rhodium as an ion and contain additives that reduce the tensile stress of the deposit. *Sulfuric acid* increases the conductivity of the bath and the *platinized titanium* serves as the anode for the electric current.

Types and Grades. All anodes are available as either rods or nuggets and have a minimal purity of 99.9 %. The proprietary additives for nickel, tin, and rhodium are all supplied as ready-to-use liquid concentrates. The remaining commodity chemicals are usually sold in liquid form as either a technical or chemically pure grade.

Uses. Nickel plating is used on printed circuit boards as an undercoat for both precious and nonprecious metals. Its main function is surfaces, such as switch and edge contacts, that normally receive heavy wear. The nickel is plated underneath a gold or rhodium plate and greatly increases wear resistance. There are two basic nickel plating baths, the nickel sulfamate bath and the modified watts nickel bath, which differ primarily on the source of nickel ions. Typical compositions for both baths are as follows:

Nickel sulfamate bath	
Nickel sulfamate	28 vol %
Boric acid	4 vol %
Nickel bromide	1 vol %
Proprietary additive	as needed
Deionized water	67 vol %
Modified watts nickel bath	
Nickel sulfate	23 vol %
Boric acid	4 vol %
Nickel bromide	1 vol %
Proprietary additive	as needed
Deionized water	72 vol %

Tin plating on circuit boards has limited application, mainly to promote solderability. The increase in the cost of precious metal plating has caused some renewed interest in tin plating as a metal etch resist.

The use of rhodium plating on circuit boards is limited to edge connectors where a low-resistance, long-wearing, oxide-free contact is required. In this type of application, rhodium replaces gold as the plated metal [7, pp. 23 – 24].

Economic Aspects. The United States printed circuit board industry consumed 45×10^3 kg of nickel anodes and 230×10^3 L of nickel plating chemicals in 1980 for electrolytic nickel plating. An additional 190×10^3 L of tin and rhodium plating chemicals was also consumed that year. The largest nickel anode supplier is International Nickel, and the two largest suppliers of nickel plating chemicals are Sel-Rex and Lea Ronal.

5. Photoresists (→ Imaging Technology)

5.1. Dry Film Photoresists

Dry film photoresists all work negatively and consist of an acid-based photopolymer layer sandwiched between a layer of polyester film on one side and either a polyolefin or a polyethylene sheet on the other side. Both cover sheets protect the photopolymer from damage by abrasion. The polyolefin or polyethylene sheet is removed as the resist is laminated to the printed circuit board. An ultraviolet source is used to expose the resist; the polyester sheet is then removed, and the resist is developed.

Ultraviolet light causes the photopolymer to polymerize and become insoluble in the developing solutions. After the dry film is developed, the remaining material acts as an etch resist with print- and etch-type circuit boards and as a plating resist with print-, plate-, and etch-type circuit boards. Once the dry film is no longer needed, it is stripped from the board by a methylene chloride solution for solvent type film, or it is stripped by a highly alkaline solution (pH 13) at ca. 49 °C for aqueous and semiaqueous type films. This process is performed only once on a printed circuit board.

Types and Grades. Three types of dry film photoresists are employed commercially: (1) solvent, (2) semiaqueous, and (3) aqueous. The solvent types are developed by using 1,1,1-trichloroethane, and semiaqueous resists are developed by using proprietary water-based solutions. Aqueous dry films are developed by using solutions of sodium carbonate or trisodium phosphate.

Uses and Economic Aspects. Dry film photoresists are used exclusively by the printed circuit board industry and are favored for both multilayer and double-sided boards with dense circuitry.

In 1980, the United States printed circuit board industry consumed ca. 1.9×10^6 m^2 of dry film photoresists while Western Europe used 9.1×10^6 m^2. The two main suppliers of this product are Du Pont and Dynachem.

5.2. Liquid Positive and Negative Photoresists

Positive photoresists are based on the photochemical conversion of an ortho diazoketone to a carboxylic acid. On exposure to ultraviolet light, these resists become less hydrophobic and are more easily attacked by the alkaline developer. The remaining unexposed areas act as an etch resist for the manufacture of integrated circuits. One of the significant advantages of this type of photoresist is that instead of swelling the film and leaching out the solubilized materials, as with negative resists, the developer removes the exposed areas of the positive resist. As a result, extremely-high-resolution images are possible because no swelling induced pattern deformation occurs.

Negative photoresists are azide-based photopolymers that polymerize when exposed to ultraviolet light. The polymerized areas become insoluble in the organic developer solutions while the nonexposed areas are dissolved. The remaining material acts as either an etching resist or a plating resist, depending on the application.

Types and Grades. All liquid photoresists are currently exposed using ultraviolet light. They are generally supplied as 100 % active materials with standard kinematic viscosities of (2, 6, 18, 30, and 70)$\times10^{-6}$ m^2/s for positive photoresists, and for negative ones, (5, 30, 45, 50, 110, and 540)$\times10^{-6}$ m^2/s.

Uses. Positive and negative photoresists are applied to the *semiconductor substrate* as a liquid that is spun to form a uniform coating and subsequently baked to a dry film. Once the positive resist is developed, the remaining material acts as an etch resist to form the desired pattern. After the etching is complete, the resist is stripped from the semiconductor wafer. Once the negative photoresist is developed, it protects the area that it covers from being etched. After the etching process is complete, the developed photoresist is stripped from the semiconductor wafer. This process is typically repeated 8 – 9 times for metal oxide semiconductor (MOS) devices and 10 – 12 times for bipolar devices.

Liquid photoresists can also be used as *etching resists* for the manufacture of thin-film circuits. However, these circuits are not classified as semiconductor devices; therefore, the resists used for this application are not included in the economic data.

Liquid photoresists can be used as either a plating or an etching resist on the inner layer of multilayer *printed circuit boards.* The developed resist prevents the etching or plating of base and precious metals on the areas that it covers. Typically, these resists are applied only once to the circuit board.

Economic Aspects. Semiconductors are the major application for positive and negative photoresists, with the United States using 300×10^3

and 800×10^3 L, respectively, and Western Europe using 76×10^3 and 95×10^3 L in 1980. The three major suppliers of positive resists are Shipley, Olin-Hunt, and Hoechst, with Kodak and Tokyo Ohka also active. The two leading suppliers of negative resists are Olin-Hunt and Kodak, with E. Merck also active.

5.3. Screening Inks

Screening inks are based primarily on vinyl – polymer resins, although other resins are also available. These inks are screened onto a printed circuit board by forcing it through a stainless steel or polyester monofilament screen that has a specific pattern that determines where the ink is deposited. The inks act as either a plating resist or an etching resist. Because of this end-use application, the screening ink must be chemically resistant to the various cleaning, plating, and etching solutions used in actual processing operations, while maintaining viscosity and thixotropic properties suitable for screen printing. When the printing process is complete, the ink is cured by either thermal drying or ultraviolet light before being used as a resist.

Types and Grades. There are two basic types of screening inks, thermally curable and ultraviolet curable, both of which can be soluble in either alkali or solvent. The inks are supplied as 100 % active material and ready for immediate use.

Uses. Screening inks are used exclusively with *printed circuit boards* as either a plating resist or an etching resist. Alkali-soluble inks are used primarily on print- and etch-type circuit boards and can withstand acid-plating baths, but not alkaline cleaning steps. These inks are removed from the board by alkaline solutions such as sodium hydroxide. Solvent-soluble inks are more versatile because they can withstand all usual plating baths and cleaning steps. As a result, these inks are more likely to be used with print, plate, and etch boards. Solvent inks are removed from the board by the use of chlorinated solvents such as 1,1,1-trichloroethane and methylene chloride.

Economic Aspects. In 1980, the United States used a total of 590×10^3 L of both thermal and ultraviolet curing screening inks for printed circuit board production. At the same time, Western Europe consumed 380×10^3 L of screening inks. Hysol and Dynachem are suppliers in both regions, with Colonial, Nuz-Dor, London Chemical, and Grace active in the United States; Coates, Sericol, and Wiederhold are active in Europe.

6. Acids and Etchants

Acids and etchants are used extensively by manufacturers of semiconductors and printed circuit boards for operations such as cleaning and etching either wafers or copper-clad laminates. Some of the most important products and their applications are listed in Table 4.

6.1. Sulfuric Acid

Sulfuric acid (H_2SO_4) is a corrosive, oily liquid that is clear, cloudy, or fuming, depending on concentration (→Sulfuric Acid and Sulfur Trioxide). Sulfur, the principal raw material employed in the manufacture of sulfuric acid, can be obtained from various sources, including (1) elemental sulfur, (2) stack gas emissions, (3) sulfuric acid sludge, and (4) pyrites and hydrogen sulfide gas.

New sulfuric acid is commonly manufactured by the contact process. This procedure involves catalytic oxidation of sulfur dioxide (SO_2) to sulfur trioxide (SO_3), which is absorbed in water. Other manufacturing methods include the chamber process, which offers slower rates of production and a lower strength and quality acid, compared to that produced by the contact process.

Grades and Properties. Sulfuric acid is produced commercially in a variety of strengths for various industrial applications. Acids containing up to 93.3 wt % H_2SO_4 are measured in degrees Baume, while acid strengths of 93.4 – 100.0 wt % are measured in terms of percent H_2SO_4. Sulfuric acid purchased by manufacturers of *semiconductors* is usually a semiconductor grade product assayed at 96 – 97 wt %

Table 4. Functions of acids and etchants

Products	CAS registry number	Formula	Applications: Semiconductors	Applications: Printed circuit boards
Acids				
Acetic acid	[*64-19-7*]	CH_3COOH	wafer etching of metals	
Boric acid	[*10043-35-3*]	H_3BO_3		acid bath stabilization
Fluoroboric acid	[*16872-11-0*]	HBF_4		tin – lead cleaner
Hydrochloric acid	[*7647-01-0*]	HCl	wafer etching	metal cleaner and regeneration of copric chloride etchants
Hydrofluoric acid	[*7664-39-3*]	HF	wafer etching	
Nitric acid	[*7697-37-2*]	HNO_3	wafer cleaning and etching	laminate cleaning
Phosphoric acid	[*7664-38-2*]	H_3PO_4	wafer etching of metals	metal cleaner
Sulfuric acid	[*7664-93-9*]	H_2SO_4	wafer cleaning and resist stripping	cleaning and etching of laminate
Etchants				
Ammoniacal solutions		NH_4^+ salts		final copper etching
Ammonium fluoride	[*16099-75-5*]	NH_4F	wafer etching	
Buffered oxide etchants			wafer etching of MOS devices	
Copper(II) chloride	[*7447-39-4*]	$CuCl_2$		copper etching of inner layer boards
Iron(III) chloride	[*7705-08-0*]	$FeCl_3$		copper etching
Others				
Hydrogen peroxide	[*7722-84-1*]	H_2O_2	wafer etching and photoresist stripping	
Ammonium persulfate	[*7727-54-0*]	$(NH_4)_2S_2O_8$		copper foil etching to provide better adhesion of electroless copper
Sodium persulfate	[*7775-27-1*]	$Na_2S_2O_8$		same as above

acid. The SEMI (Semiconductor Equipment and Materials Institute) specifications for sulfuric acid are available [5].

In addition to semigrade sulfuric acid, extremely low particulate products are also available to semiconductor manufacturers. These materials meet or exceed specifications for semigrade sulfuric acid while being virtually free of suspended matter.

Manufacturers of *printed circuit boards* generally purchase technical grade sulfuric acid. Specifications for particulate content and purity of these products are not typically as high as specifications for acid used by the semiconductor industry.

Uses. During the manufacturing of *semiconductors,* the wafer is cleaned numerous times with sulfuric acid to remove microscopic dust and other contaminants from the substrates surface. For example, during the masking operation alone, wafers may be cleaned several times before progressing to the next manufacturing step. Other applications for sulfuric acid include mixture with hydrogen peroxide to form Caro's acid, which is a wafer cleaner and resist stripper.

Printed Circuit Boards. Sulfuric acid is used as a (1) cleaner, (2) etchant, and (3) constituent of electrolytic copper plating baths. As a cleaner, the acid removes foreign contaminants formed from contact of an etchant of other material with the laminate surface. For example, an ammonium persulfate etch in contact with copper can produce copper ammonium sulfate, which can form a film on the board's surface. This film is readily removed by dipping the board in a sulfuric acid bath prior to the next manufacturing step.

Other applications for this electronic chemical include acid – copper electrolytic plating, whereby sulfuric acid is added to a copper sulfate bath for anode corrosion to replenish the copper sulfate level of the solution while also increasing bath conductivity.

6.2. Hydrofluoric Acid

Hydrofluoric acid (HF) in the anhydrous form is a fuming, corrosive liquid that can cause serious

burns on skin contact. The acid is manufactured by the reaction of sulfuric acid and fluorspar (calcium fluoride) to produce hydrogen fluoride gas and calcium sulfate. After absorption in water, the acid is concentrated by distillation, forming anhydrous hydrogen fluoride. Aqueous grades are then made by dilution with water.

Grades and Properties. Hydrofluoric acid purchased by manufacturers of semiconductors is often a semigrade product assayed at 48.8 – 49.2 % HF. Specifications for the semiconductor grade chemical according to SEMI are available [5].

Low particulate HF is also available to manufacturers of semiconductors. This acid meets or exceeds the semiconductor grade specifications.

Uses. Hydrofluoric acid is employed primarily to etch conductive paths on the surface of the wafer. The acid is often mixed with ammonium fluoride by the customer to form a buffered oxide etch, particularly for MOS devices. Various concentrations of ammonium fluoride and hydrofluoric acid are used for this purpose; however, a solution containing six parts of ammonium fluoride to one part of hydrofluoric acid is preferred by most semiconductor fabricators.

6.3. Ammoniacal Solutions

Ammoniacal solutions are proprietary formulations that typically contain a blend of various ammonium-based compounds. For example, these proprietary solutions are generally composed of hydroxides, chlorides, carbonates, phosphates, and nitrates of ammonia. The exact proportion of the individual chemicals to form the finished ammoniacal solution is kept confidential by the specialty suppliers.

Grades and Properties. Ammoniacal solutions are specifically formulated to meet the demands for copper etching set forth by the printed circuit board industry. These products generally differ in formula mass, appearance, and other properties, depending on the proprietary product analyzed. However, most blends have a pH of 8 – 9 and a density of 12 g/cm^3.

Uses. Ammoniacal solutions are used only as final copper etchants by manufacturers of printed circuit boards. Early versions of alkaline etchants, such as the ammoniacal solutions, were used for batch etching; the etch rates decreased as the copper content in the etching solutions increased. However, newer products were developed by adding oxidizing agents to speed the etching rate and increase the copper capacity of the solution at a constant temperature. Although batch operations are still employed, continuous systems have become popular. A typical alkaline etching installation operates continuously and in a closed loop. System components include (1) a standard spray etcher, (2) metering pumps, (3) control modules, and (4) storage tanks.

As previously mentioned, various ammonium compounds are important in formulating ammoniacal solutions (Table 5). These ammonium compounds serve to hold the copper being etched in solution and to increase the etch rate. Other important components of these proprietary solutions include copper ions, which react with and dissolve the metal by oxidation, as indicated in Table 5. Generally the solutions formulated with these chemicals are compatible with metals such as gold, nickel, silver, tin, tin – nickel, and particularly tin – lead.

6.4. Nitric Acid

Nitric acid (HNO_3) is strong, reactive, corrosive, and colorless in pure (100 %) form. Pure nitric acid is unstable and decomposes to nitrogen dioxide, which gives concentrated solutions a yellow-brown color; thus, commercial products typically contain various proportions of water.

Commercial production of nitric acid involves oxidation of ammonia first to form nitric oxide, and then nitrogen dioxide, which is absorbed in water to give the acid. Concentrated nitric acid is manufactured primarily by dehydration with sulfuric acid. In this procedure sulfuric acid (98 – 99 %) is mixed with sulfur trioxide (SO_3) and 60 % nitric acid in a concentrator. The sulfuric acid absorbs the water, resulting in nitric acid of ≥ 95 % strength. The concentration of the remaining sulfuric acid ranges from 60 to 70 %.

Table 5. Compounds important in formulating ammoniacal solutions

Component	CAS registry number	Formula	Function
Ammonium hydroxide	[*1336-21-6*]	NH_4OH	holds copper in solution
Ammonium chloride	[*12125-02-9*]	NH_4Cl	increases etch rate, copper holding capacity, and solution stability
Ammonium carbonate	[*506-87-6*]	$(NH_4)_2CO_3$	acts as a buffer, retains clean solder holes
Ammonium phosphate	[*7783-28-0*]	$(NH_4)_2HPO_4$	retains clean solder
Ammonium nitrate	[*6484-52-2*]	NH_4NO_3	increases etch rate and retains clean solder
Copper ion		Cu^{2+}	reacts with and dissolves metallic copper by acting as an oxidizing agent
Sodium chlorate	[*7775-09-9*]	$NaClO_3$	acts as an oxidizing agent that reacts with and dissolves metallic copper

Grades and Properties. Nitric acid is manufactured in several concentrations. Acids containing up to 67.2 wt % nitric acid are described in degrees of Baume, whereas acids of 70 – 95 wt % (or greater) concentration are commonly referred to in terms of percent HNO_3. The semiconductor grade of nitric acid used by manufacturers of semiconductors contains ca. 70 wt % HNO_3; the SEMI specifications for this acid are available [5].

Grades of nitric acid with a low particulate content are also available to the semiconductor industry. Manufacturers of printed circuit boards often buy an electronic- or technical-grade of nitric acid. Specifications of particulate content for these products are generally inferior to those of acid purchased by the semiconductor industry.

Uses. Nitric acid is used to clean foreign contaminants from the wafer's surface during selected steps in the manufacture of *semiconductors.* In addition, this material is also blended with other acids, such as acetic and hydrofluoric acid, to etch away metals, such as tantalum, simply by reacting with them.

During the manufacture of *printed circuit boards,* the board itself is often cleaned. Nitric acid is frequently used for this operation.

6.5. Hydrogen Peroxide

Hydrogen peroxide (H_2O_2) is a nonviscous, clear liquid with a faint blue-green color. Hydrogen peroxide has a slightly sharp odor and is miscible in all proportions with water.

Several manufacturing processes exist to make hydrogen peroxide; however, the current route involves successive hydrogenation and oxidation of organic diketones. For example, ethyl anthraquinone is hydrogenated to ethyl anthrahydroquinone, which is then oxidized to regenerate the ethyl anthraquinone and hydrogen peroxide.

Grades and Properties. Commercially, aqueous solutions of hydrogen peroxide are available in concentrations of 27 – 70 wt %. Most of this material purchased by the semiconductor industry contains 30 – 32 wt % hydrogen peroxide. The SEMI specifications for hydrogen peroxide are available [5].

Grades of hydrogen peroxide with a low particulate content are also available to semiconductor manufacturers. Technical grades are often preferred by the producers of printed circuit boards.

Uses. Hydrogen peroxide is commonly used by *semiconductor* manufacturers to clean wafer surfaces of foreign contaminants or to remove a photoresist. Quite often sulfuric acid is mixed with hydrogen peroxide (4 : 1 ratio) to form Caro's acid [*7722-86-3*], peroxymonosulfuric acid, for maximum cleaning efficiency during these operations.

Hydrogen peroxide is often purchased individually by manufacturers of *printed circuit boards* to regenerate etching solutions of copper chloride. In this procedure, the laminate is dipped into a copper chloride bath. The hydrogen peroxide acts as an oxidizing agent to free chlorine ions, which etch copper from the laminate.

In addition, manufacturers of printed circuit boards add hydrogen peroxide to proprietary etchants based on sulfuric acid to etch copper before electroless copper is deposited.

6.6. Proprietary Peroxy and Sulfuric Etchants

Proprietary etchants are based on either hydrogen peroxide or sulfuric acid. The formulations contain specialty additives for stability.

Proprietary peroxy etchants are composed primarily of hydrogen peroxide. Special additives act as stabilizers to retard degradation of the base chemical. The concentration of these additives is generally 1 – 4 wt % of the total product.

Proprietary sulfuric etchants usually contain sulfuric acid. Specialty additives, primarily stabilizers, extend the life of the product during etching procedures.

Grades and Properties. Properties of the proprietary peroxy and sulfuric etchants depend primarily on the base chemicals. For example, properties of the peroxy etchants are directly related to hydrogen peroxide, the base component. The relative molecular mass of hydrogen peroxide is 34 and its relative density is ca. 1.5 times that of water. Sulfuric acid, the base chemical for the sulfuric etchants, has a substantially higher molecular mass of 98.1 and a density of ca. 1.83, depending on the concentration.

Uses. Before being used as an etchant by the printed circuit board industry, these proprietary products may be further compounded by the customer, depending on the product purchased. For example, a stabilized peroxy etchant requires the addition of water and sulfuric acid (technical or reagent grade) at the customer's facility. A typical formulation of the finalized peroxy product may contain 82 vol % water (deionized), 11 vol % sulfuric acid, and a 7 vol % proprietary peroxy etchant.

Conversely, a manufacturer of printed circuit boards buying stabilized sulfuric acid would add water and hydrogen peroxide to get the final formulation.

In addition to stabilized hydrogen peroxide or sulfuric acid, specialty additive formulations are also available. These products consist primarily of the same materials used to give stability to the preceding base chemicals; however, these products require addition of sulfuric acid and hydrogen peroxide by the customer.

Once the etchant is formulated by the manufacturer of printed circuit boards, it is then used primarily to etch copper before electroless copper is deposited. Because of the etching action of these products, electroless copper adheres more strongly to the copper foil on the laminate simply by its abrasive action. Sodium and ammonium persulfate etchants also compete with the peroxy products in this end use.

In addition to acting as an etch, proprietary peroxy etchants are used less extensively to remove unwanted copper from the board in a later production process, leaving the final circuitry untouched. Other etchants used more frequently in this application include ammoniacal solutions and iron(III) and copper(II) chlorides.

Once the customer formulates the proprietary etchant with sulfuric acid or hydrogen peroxide (or both), the copper is etched by formation of copper sulfate:

$$Cu + H_2O_2 + H_2SO_4 \rightarrow CuSO_4 + 2\,H_2O$$

Cooling the etching solution to room temperature allows a pure grade of copper sulfate to be extracted for reclamation of copper.

6.7. Ammonium Fluoride

Ammonium fluoride (NH_4F) is a white crystalline salt. It often has a strong ammonia odor because it tends to decompose to ammonia and the more stable ammonium hydrogen fluoride ($NH_4F \cdot HF$). Ammonium fluoride can be produced easily by mixing aqueous ammonia with ammonium hydrogen fluoride in equimolar proportions.

Grades and Properties. Ammonium fluoride employed by manufacturers of semiconductors contains 40 wt % NH_4F. The SEMI specifications for this material are available [5].

Uses. Ammonium fluoride is generally mixed with hydrofluoric acid by manufacturers of semiconductors to etch the surface of wafers, particularly those used to make MOS devices. These buffered oxide etches, made captively, often contain six parts of ammonium fluoride to one part of hydrofluoric acid.

6.8. Persulfates

Ammonium persulfate $(NH_4)_2S_2O_8$ and sodium persulfate $(Na_2S_2O_8)$ employed by manufacturers of printed circuit boards are white crystalline materials with strong oxidizing characteristics. These products are typically produced by electrolytic oxidation of the appropriate hydrogen sulfate salt.

Grades and Properties. Both ammonium and sodium persulfates are high-purity salts easily solubilized in water and other materials. The molecular mass of sodium persulfate is 238, whereas that of ammonium persulfate is somewhat less at 220. The amount of active oxygen differs between each product type, but generally is 6 – 7 wt %.

Uses. Persulfates are used by the *printed circuit board* industry mostly as a cleaner and etchant prior to the deposition of electroless copper. Because they are strong oxidizing agents, these products roughen or abrade the surface of the board, enabling electroless copper to adhere more strongly without attacking resists or plastics used as the circuitry base. Persulfates are applied in either continuous or batch methods, depending on the customer's operation.

Solutions based on persulfates have an etch rate of 0.76 – 2.5 nm/min, depending on the temperature and copper content of the solution, which can be $\geq$ 7.8 mg/L. The persulfate concentration can also affect the etch performance of the finished persulfate solution.

Ammonium persulfate can be used to etch other metals besides copper, including materials such as aluminum, beryllium, and brass. The ratio of the compounds in the mixture depends on the customer's operation. A 20 % solution is made simply by adding 0.2 kg of ammonium persulfate per liter of water in a sump or dissolving tank.

Solutions are often catalyzed with materials such as mercuric chloride to achieve optimal etch rates or phosphoric acid to eliminate incomplete etching of copper next to solder-plated conductors.

Sodium persulfate solutions are also prepared according to the customer's preference. For example, solutions often contain 0.15 kg of $Na_2S_2O_8$ per liter of warm water. Small quantities of phosphoric or sulfuric acid can be added on initial makeup for more aggressive cleaning solutions.

6.9. Other Acids and Etchants

A variety of other acids and etchants are employed by manufacturers of semiconductors and printed circuit boards in their production processes. Among the more important are acetic, phosphoric, and hydrochloric acids, whereas other material, such as formulated buffered oxide etches (BOE) and iron(II) chloride, are also significant.

Acetic Acid (→ Acetic Acid). The three significant processes employed to produce acetic acid are (1) methanol carboxylation, (2) butane oxidation, and (3) acetaldehyde oxidation. Acetic acid purchased by manufacturers of semiconductors is usually a semigrade product assayed at 99.7 wt % CH_3COOH. The SEMI specifications for acetic acid as used in phosphoric etchants are available [5].

Acetic acid is used by manufacturers of semiconductors only where it is mixed with nitric and phosphoric acids to serve as a metal etchant. Semigrade acetic acid sells for ca. \$ 2.20/kg (\$ 1/lb.), and it is usually shipped in 2.3-kg (5-lb.) bottles, with six to a case.

Phosphoric Acid. (→ Phosphoric Acid and Phosphates) Phosphoric acid is a corrosive, syrupy liquid that can cause burns on contact with the skin. It can be made by reacting elemental phosphorus with oxygen to form phosphorus oxides, which are then dissolved in water to form the acid. An alternate process involves the reaction of acids such as sulfuric or nitric acid with phosphate rock to dissolve the calcium phosphate. Phosphoric acid purchased by manufacturers of semiconductors is usually a semigrade product assayed at 85 – 87 wt % H_3PO_4. The SEMI specifications for this chemical are available [5].

Technical grades of phosphoric acid have lower purity and a higher particulate content than the semigrade products and as a result are used less frequently.

Manufacturers of semiconductors mix phosphoric acid with nitric and acetic acids and use the mixture as a metal etchant, whereas the printed circuit board industry employs the acid by itself as a metal cleaner. Semigrade phosphoric acid sells for ca. $ 1.50/kg ($ 0.68/lb.), and it is usually packaged in 6.35-kg (14-lb.) bottles, with four to a case. Technical grade acid is somewhat less expensive at $ 0.46/kg ($ 0.21/lb).

Hydrochloric Acid. (→ Hydrochloric Acid) Hydrochloric acid is a strong, highly corrosive acid, primarily produced as a byproduct from the manufacture of organochlorine chemicals. The semiconductor industry buys a semigrade product assayed to contain a minimum of 37 wt % acid. The SEMI specifications are available [5].

In addition to semigrade acid, products with an extremely low particulate content are also available to manufacturers of semiconductors. Technical- or reagent-grade hydrochloric acid is commonly employed by the printed circuit board industry.

Hydrochloric acid is used primarily as a wafer etchant by semiconductor manufacturers. The printed circuit board industry employs HCl as a metal cleaner and as a source of chlorine ions for copper(II) chloride etchants. Semigrade acid sells for ca. $ 1.28/kg ($ 0.58/lb.) in 4.54-kg (10-lb.) containers, with four to a case, whereas technical-grade acid is considerably less expensive at $ 0.18/kg ($ 0.08/lb).

Fluoroboric Acid. (→ Boron Compounds, Chap. 2.) Fluoroboric acid with a density of ca. 1.38 g/cm^3 has properties similar to those of hydrofluoric acid, including a corrosive effect on glass. This acid is used primarily by the printed circuit board industry as a tin – lead cleaner, and the cost is ca. $ 1.32/kg ($ 0.60/lb).

Mixed Acid Etchants. Mixed acids are specially blended products usually containing nitric, hydrofluoric, and acetic acids. Properties of these products depend on the proprietary proportions of each component. A mixture of acids is used by the semiconductor industry as a metal etchant; cost ranges from $ 1.52 to $ 2.29/kg ($ 0.69 to $ 1.04/lb). The SEMI specifications for mixed acid etchants are available [5].

Chromic – Sulfuric Acid Etchants. Chromic – sulfuric etchants are specially blended products containing chromic and sulfuric acids with the exact proportion of each component determined by the formulator. These products are used sparingly by printed circuit board manufacturers to remove epoxy smears in the etch-back process and as a final copper etchant. Chromic – sulfuric blends usually cost ca. $ 0.53/L ($ 2/gal).

Boric Acid. (→ Boric Oxide, Boric Acid, and Borates, Chap. 3.) Boric acid is used by printed circuit board manufacturers for acid bath stabilization. The cost of this product is ca. $ 0.14 kg ($ 0.30/lb).

Buffered Oxide Etchants. Buffered oxide etchants (BOE) are specially blended products often containing six parts of ammonium fluoride to one part of hydrofluoric acid. These products are used primarily as etchants, particularly for MOS devices, by semiconductor manufacturers. Formulated BOE etchants purchased by this industry cost ca. $ 1.83/kg ($ 0.83/lb.) in 1980. The SEMI specifications for this product are available [5].

Copper(II) Chloride. (→ Copper Compounds, Chap. 4.) Copper(II) chloride etching solutions contain components such as hydrochloric acid, sodium chloride, ammonium chloride, water, and copper(II) chloride crystals. Specific formulations of these commodity chemicals depend on performance results experienced by the individual manufacturer of printed circuit boards during final etching operations. For example, chloride ions can be provided by several sources, including hydrochloric acid, sodium chloride, or ammonium chloride, to solubilize the relatively insoluble copper(I) chloride formed by the etching action of the copper (II) chloride solution on copper. The use of such chloride ions assists in maintaining a stable etch rate. In addition, copper(I) chloride can be oxidized to copper(II) chloride by electrolytic processes or by direct chlorination, as follows:

$$Cu_2Cl_2 + Cl_2 \longrightarrow 2\,CuCl_2$$

Copper(II) chloride solutions are used mostly to etch inner layers of multilayer boards. These

solutions are also used to process print and etch boards. Resists, such as screening inks, dry film, and tin – nickel, are compatible with this etchant, whereas other materials, such as tin – lead and tin boards, are unsuitable.

Table 6. Consumption of acids and etchants in electronics in the United States, 1980

Product	Consumption, 10^3 t		
	Semiconductors	Printed circuit boards	Total
Acids			
Sulfuric	16.8	27.2	44.0
Nitric	7.7	2.0	9.7
Hydrochloric	1.4	7.7	9.1
Hydrofluoric	8.2		8.2
Proprietary		3.1	3.1
Phosphoric	1.7	1.3	3.0
Acetic	2.3		2.3
Fluoroboric		2.1	2.1
Chromic – sulfuric		1.0	1.0
Mixed	0.5		0.5
Boric		0.4	0.4
Subtotal	38.6	44.8	83.4
Etchants			
Ammoniacal solutions		48.1	48.1
Copper(II) chloride		12.2	12.2
Iron(III) chloride		8.1	8.1
Hydrogen peroxide	5.4	1.4	6.8
Persulfates		5.3	5.3
Ammonium fluoride	3.7		3.7
Buffered oxide etchants	2.0		2.0
Subtotal	11.1	75.1	86.2
Total	49.7	119.9	169.6

Iron(III) Chloride (→ Iron Compounds). Iron(III) chloride etchants consist primarily of $FeCl_3$ in water with concentrations ranging from 28 to 42 wt %; wetting and antifoam agents also are typically added. These solutions are widely used in the printed circuit board industry as final etchants for copper, copper alloys, and steel. In addition the iron(III) chloride etchant is compatible with screening inks and photoresists, but not with solder or tin-plated boards.

Solutions of iron(III) chloride formulated with additives by specialty suppliers provide fast and even etching, partly because of the addition of strong oxidizers and surface wetting agents. Over the years, suppliers of these products have greatly extended the useful life and uniformity of etch rates provided by these products. Iron(III) chloride etching solutions sold for ca. \$ 0.18/L (\$ 0.70/gal) or ca. \$ 0.13/kg (\$ 0.06/lb.) in 1980.

Economic Aspects. Total demand for acids and etchants by the electronics industry in the United States was 169.6×10^3 t in 1980. The printed circuit board industry used 71 % of the total (119.9×10^3 t), and the semiconductor industry consumed the balance. A breakdown of consumption by product is given in Table 6.

The leading suppliers of semiconductor-grade acids and etchants in the United States are General Chemical, Ashland Chemical, and Mallinckrodt. Technical-grade chemicals are provided by numerous bulk chemical manufacturers. Ammoniacal solutions are sold mainly by Olin-Hunt, MacDermid, and Southern California Chemical. The three major suppliers of proprietary acid mixtures are Electrochemicals, Shipley, and MacDermid. The major supplier of persulfates in the United States is FMC.

7. Atmospheric Gases

Nitrogen [*7727-37-9*], N_2, *bp* −196 °C, is a chemically inert, odorless, colorless, tasteless, diatomic gas (→ Nitrogen). It makes up 80 vol % of the air we breathe. Nitrogen reacts with other elements only at high temperature and pressure.

Nitrogen is produced in air-separation plants by liquefaction and subsequent fractionation of air into its major components, i.e., nitrogen, oxygen, and small amounts of argon. In some plants small quantities of neon, krypton, and xenon may also be recovered, whereas other gases in the air, such as carbon dioxide, helium, and hydrogen, are usually vented. Generally, the most economical production ratio is 2.4 parts of nitrogen to 1 part of oxygen, with excess N_2 used to clean alternate compressors within the plant.

Grades and Properties. Nitrogen has a molecular mass of 28.01 and a specific volume of 0.862 m^3/kg. Typically, gas sold to the semiconductor industry exceeds 99 % in purity. The SEMI specifications for liquid nitrogen used in bulk by the semiconductor industry are available [5].

Uses. Nitrogen is essential in many production processes and is by far the most widely used atmospheric gas among manufacturers of semiconductors in the United States. For example, nitrogen is commonly found in furnaces, epi (epitaxial) reactors, and ion implanters as an inert atmosphere to protect against impurities such as

oxygen. Additional uses for this versatile gas include serving as the transportation medium in air tracts and the driving force in air guns. Nitrogen is supplied to customers by several means, including (1) pipelines serving either single or multiple facilities, (2) air-separation plants located on site, and (3) merchant bulk deliveries.

Hydrogen [*1333-74-0*], H_2, is a colorless, odorless, and tasteless gas that is lighter than air and practically insoluble in water (→ Hydrogen). Commercial processes for hydrogen production include electrolysis, ammonia dissociation, propane re-forming, partial oxidation of hydrocarbons, and steam re-forming of natural gas.

Types and Grades. Hydrogen purchased by manufacturers of semiconductors generally has a minimal purity of 99.9 % The SEMI specifications for impurity levels in bulk hydrogen are available [5].

Uses. Hydrogen is used by the semiconductor industry to create a reducing atmosphere, particularly in manufacturing bipolar devices. For example, with metals such as aluminum, any oxide present can be reduced to seal the metallic surface before becoming a component of the integrated circuit. An additional, but less common, application for hydrogen involves mixture of gas with carbon tetrafluoride for reactive ion etching (RIE).

Argon [*7440-37-1*], Ar, *bp* −186 °C, *fp* −198.4 °C is a colorless and odorless gas (→ Noble Gases). Virtually all commercial production of argon is the result of oxygenic separation of atmospheric gases.

Types and Grades. Argon purchased by manufacturers of semiconductors is almost 100 % pure. The SEMI specifications for the allowable impurity levels are available [5].

Uses. Argon is used primarily by the semiconductor industry as an inert atmosphere for growing single silicon cystals (→ Crystal Growth; → Silicon). Argon is also used as an atmosphere during ion-implant procedures and during annealing, a process to repair substrate damage after ion implantation takes place.

Oxygen [*7782-44-7*], O_2, is a colorless gas that forms oxides with all elements except some of the noble gases (→ Oxygen). Almost all commercial oxygen is produced by fractional distillation of air.

Types and Grades. Oxygen purchased by manufacturers of semiconductors is high in quality with a minimal purity of 99.6 %.

Uses. Oxygen is used by manufacturers of semiconductors to produce passivation layers of silicon dioxide on silicon substrates, particularly for MOS devices. Additional uses of this gas include plasma stripping of photoresists.

Economic Aspects. Consumption of the four atmospheric gases discussed in this chapter is shown in Table 7.

Table 7. Consumption of atmospheric gases by the semiconductor industry, 1980

Gas	Consumption, 10^6 m^3	
	United States	Western Europe
Nitrogen	1076.0	138.8
Hydrogen	31.2	6.4
Argon	7.1	2.0
Oxygen	21.5	2.6

These gases are typically sold by the same companies. Several major suppliers are active in both the United States and Western Europe, including Air Products, BOC/Airco, and L'Air Liquide. The Linde Division of Union Carbide is an important supplier of atmospheric gases in the United States, and Messer Griesheim is a big supplier in the Federal Republic of Germany.

8. Photoresist Adjuncts

8.1. Photoresist Strippers

Strippers are chemicals used to remove photoresist after the etching or plating process is complete. Unlike developers, which remove solubilized photoresist, strippers remove the hardened unsolubilized photoresist without damaging the underlying material.

Types and Grades. The three types of strippers for *semiconductor photoresists* are (1) oxygen in a plasma state, (2) phenolic-based formulations, and (3) nonphenolic formulations, which are based on either sulfonic acid or chromic acid. All of these products are sold as electronic-grade material. Strippers for *printed*

circuit board photoresists include commodity chemicals, such as methylene chloride and sodium hydroxide, as well as proprietary formulations based on these chemicals. These printed circuit board strippers are available as technical-grade materials.

Uses. *Semiconductor* photoresist stripping with oxygen is accomplished by placing the wafers in a vacuum chamber, where the gas passes through a radio frequency electrode to form a highly ionized gas or plasma. The plasma contacts the photoresist, causing a chemical reaction that oxidizes the resist to ash; the resist ash is then rinsed from the water surface. On the other hand, chemical resist stripping involves immersion of the wafer in a stripping bath for 30 – 60 s.

All *printed circuit board* resists are stripped by immersion techniques. Solvent-based strippers usually operate at room temperature and require 1 – 2 min for complete photoresist removal, while alkaline-based strippers operate at 49 – 60 °C and require from 30 s to 3 min for complete photoresist removal.

Economic Aspects. The total consumption of strippers for electronics in the United States was 12.8×10^6 L in 1980. Of this total, 10.9×10^6 L was used by the printed circuit board industry, as indicated in Table 8.

Table 8. Consumption of strippers by the electronics industry

Product	Consumption, 10^6 L		
	Printed circuit boards	Semiconductors	Total
Solvent	8.3		8.3
Alkaline	2.6		2.6
Phenolic		1.5	1.5
Nonphenolic		0.4	0.4
Total	10.9	1.9	12.8

Many companies supply photoresist strippers for printed circuit boards, but the three largest suppliers are Chemical Solvent, J & S Laboratories, and Inland Specialty Chemical. For semiconductor photoresist strippers, Industri-Chem is the major supplier of phenolic-based products, General Chemical is an important supplier of both phenolic and nonphenolic products, and EKC Technology specializes in nonphenolic products.

8.2. Dry Film Photoresist Developers

Dry film photoresist developers are either solvent- or alkaline-based products that remove the soluble, nonexposed areas of the resist prior to the plating process.

Types and Grades. The two types of dry film developers are commodity solvents and proprietary formulations. Usually technical-grade 1,1,1-trichloroethane is the solvent used to develop solvent-processable dry films. Proprietary developers are used with aqueous- and semiaqueous-processable dry films.

Uses. Dry film photoresists are developed by immersing the printed circuit board in a solution of aqueous developer. The time required for optimum development varies with the thickness of the resist and the temperature of the bath, but normally 30 – 60 s is needed.

Economic Aspects. In 1980, the United States printed circuit board industry used a total of 14.8×10^6 L of dry film photoresist developers. Approximately 11.4×10^6 L consisted of 1,1,1-trichloroethane, and the balance was proprietary formulations. Dow and PPG are the major suppliers of 1,1,1-trichloroethane, whereas Du Pont and Dynachem are the major suppliers of proprietary developers.

8.3. Positive Photoresist Developers

Positive photoresist developers are alkaline-based solutions that remove the soluble exposed areas of the resist by an etching process. Development of the resist is accomplished by either a spray or immersion technique.

Types and Grades. The two types of positive photoresist developers are commodity chemicals, such as sodium and potassium hydroxide, and proprietary alkaline-based formulations. Electronic grades of sodium and potassium hydroxide are normally used, while proprietary developers are available only in an electronic grade.

Uses. *Semiconductor* wafers can be either immersed in a developer solution or sprayed with the solution. Immersion is favored with positive photoresist developers because line resolution is usually better with this technique. The developing time required for immersion is ca. 1 min. Spray techniques offer faster speed than that obtained with the immersion method, with a typical development time of 15 s.

Positive photoresists used on *printed circuit boards* are usually developed by immersion techniques.

Economic Aspects. In 1980, a total of 704×10^3 L of positive photoresist developers was consumed in the United States. Of the total, 643×10^3 L consisted of proprietary developers and the rest were either sodium or potassium hydroxide. Proprietary developers are sold by the photoresist supplier, Shipley, Hoechst, Olin-Hunt, and Kodak; firms such as Ashland Chemical, J. T. Baker, and General Chemical supply semiconductor grade hydroxides.

8.4. Negative Photoresist Developers

Negative photoresist developers are either solvent or solvent-based products that swell the photoresist film after the imaging process. The developer removes the soluble, unexposed area of the resist by a leaching process. The resist is developed by either a spray or immersion technique. A solvent rinse is used after the film is developed to remove any residual developer and to reduce swelling of the remaining photoresist.

Types and Grades. The two types of negative photoresist developers are commodity solvents, such as xylene, 1,1,1-trichloroethane, trichloroethylene (TCE), and stoddard solvent proprietary formulations. Both electronic-grade and reagent-grade xylene is used by the electronic industry, while only electronic-grade proprietary formulations are available. The proprietary products are based on xylene, with stabilizers added. The printed circuit board industry usually uses technical-grade commodity solvents. The SEMI specifications for xylene are available [5].

Uses. Usually electronic-grade xylene or proprietary formulations are used to develop photoresists on *semiconductor wafers,* although some reagent-grade xylene is also used. Semiconductor wafers can either be immersed in a developer solution or have the solution applied by spraying. Spray systems offer the benefit of speed and provide a continuous flow of clean solvent, while batch immersion tends to give finer resolution. The developing time with spray systems ranges from 15 to 30 s compared with 60 – 90 s for batch immersion.

Printed circuit boards using a Kodak or Hunt negative resist can be developed either in a vapor degreasing chamber using trichloroethylene or by immersion in a proprietary developer. Dynachem resists are attacked by trichloroethylene and must be developed by immersion in either 1,1,1-trichloroethane or a proprietary solution. Development time with a vapor degreaser ranges from 3 to 4 min, while immersion in a formulated developer usually requires 20 – 30 s. A vapor degreaser can develop many boards simultaneously, but immersion is usually done one board at a time.

Economic Aspects. The use of negative photoresist developers in the United States was 1.89×10^6 L in 1980, the vast majority being used in semiconductor applications. Xylene was the preferred product, representing 90 % of all consumption, with proprietary formulations accounting for most of the balance. Firms such as Ashland Chemical, J. T. Baker, and General Chemical supply semiconductor-grade xylene. Photoresist manufacturers, including Olin Hunt, Kodak, and E. Merck, supply the proprietary formulations.

8.5. Photoresist Adhesion Promoters

1,1,1,3,3,3-Hexamethyldisilazane [*999-97-3*], (HMDS), $(CH_3)_3SiNHSi(CH_3)_3$, is an organosilicon compound that is used to promote adhesion of photoresists on silicon and silicon oxide surfaces during manufacture of semiconductor devices. 1,1,1,3,3,3-Hexamethyldisilazane accomplishes increased photoresist adhesion by reacting with surface hydroxyl groups, which normally repel photoresists, to form hex-

amethyldisiloxane, which does not repel photoresists.

The three methods for applying HMDS to the surface of the semiconductor substrate are evaporation, spinning it on, and complete immersion. In the *evaporative method,* elevated temperature causes HMDS to vaporize and subsequently contact the wafer surface. This technique generally uses 100 % active HMDS, although less concentrated solutions can also be used; a tray of wafers can be treated simultaneously. Several industry sources believe this method to be the most cost effective of the three.

The *spin-on method* applies the liquid HMDS directly to the wafer just prior to applying the photoresist. This approach uses solvent mixtures of HMDS, requiring that the solvent be compatible with the photoresist thinner. Usually solvents such as xylene and stoddard solvent are used with negative resists, while ethylene glycol, fluorocarbon 113, or cellusolve acetate are used with positive resists. Carbon tetrafluoride is compatible with both types of resists. The spin-on technique provides a uniform coating of HMDS on the wafer, but this method can treat only one wafer at a time.

Complete immersion requires dipping the wafer into a bath of HMDS and solvent. This process is not widely used because it offers little control over the amount of HMDS coated on each wafer.

Types and Grades. 1,1,1,3,3,3-Hexamethyldisilazane is available in concentrations ranging in activity from 5 to 100 %. In solutions, HMDS is normally mixed with solvents such as xylene, stoddard solvent, ethylene glycol, and carbon tetrafluoride. All HMDS is sold as electronic-grade material, indicating that the level of each metal impurity is < 1 ppm.

Uses. The semiconductor industry uses HMDS exclusively as an adhesion promoter. The use of HMDS to treat oxide surfaces is covered by a patent assigned to IBM [8]. Licenses under this patent are available from IBM on reasonable terms and conditions.

Economic Aspects. In 1980, ca. 303×10^3 L of 100 % active HMDS was consumed by the semiconductor industry in the United States. The leading suppliers are PCR, KTI, Mallinckrodt, and Ashland Chemical.

9. Cleaners and Specialty Materials

Tin – Lead Strippers. Tin – lead strippers are based mostly on hydrogen peroxide, a clear liquid with a slightly sharp odor. Although not specifically identified, stabilizers are usually included in the formulation to prevent degradation of the base chemical. The average density of tin – lead strippers based on hydrogen peroxide is estimated to be 1.16 g/cm^3. Compositions of the less frequently used products that are not based on peroxide are unavailable.

Uses. Manufacturers of printed circuit boards frequently employ tin – lead stripping to remove tin – lead from edge connectors or tops without damaging the copper or laminate itself. This procedure promotes adhesion of the nickel plate on the copper surface prior to gold striking. Strippers currently available are capable of removing 0.013 mm of tin – lead in < 1 min or up to 135 g of tin – lead per liter. Other products are specifically designed just to remove tin to prevent subsequent poisoning of the nickel plate by enhancing adhesion.

Copper Cleaners. Copper cleaners are generally acid- or alkaline-based products sold in concentrate form. As expected, properties such as density and pH are directly related to the base chemical. For example, the density of acid concentrates is ca. 1.08 g/cm^3 and the pH is usually < 4. The exact amount of water or other solvents mixed with copper cleaners depends on operating results experienced by the individual operator at each company.

Uses. The printed circuit board industry employs copper cleaners for a variety of jobs including removal of organic and inorganic soils, such as fingerprints, light oils, or tarnish, from copper surfaces. Boards are generally sprayed or soaked with the copper cleaner followed by a water rinse.

Tin – Lead Cleaners. Tin – lead cleaners are generally acid-based products containing additives to reduce degradation of components during adverse operating conditions. Some products are employed in full strength, and others

are frequently diluted with water before being applied.

Properties of tin – lead cleaners vary by product, depending on the base chemicals. For example, densities of acid-based products can range from 1.08 to 1.14 g/cm^3 and the pH is typically < 1.

Economic Aspects. In 1980, the printed circuit board industry in the United States consumed 9.0×10^6 L of the following cleaners and specialties (in 10^6 L):

Tin – lead strippers	3.4
Tin – lead cleaners	3.0
Copper cleaners	2.6

Numerous companies supply these products in the United States. The leading ones are Chemelex, J & S Laboratories, MacDermid, Enthone, Argus International, and Electrochemicals.

10. Specialty Gases

10.1. Silicon Gases

Silicon gases are used to deposit silicon and silicon compounds onto silicon substrates by chemical vapor deposition. These deposits or epitaxial layers are part of the finished semiconductor device. Four silicon gases are used to form the epitaxial layers: silicon tetrachloride, trichlorosilane, dichlorosilane, and silane.

Silicon(IV) tetrachoride [*10026-04-7*], $SiCl_4$, tetrachlorosilane, silicon(IV) chloride, is manufactured as a liquid by an exothermic reaction of silicon carbide with chlorine as given in the following equation:

$$SiC + 2\,Cl_2 \rightarrow SiCl_4 + C$$

The major use of $SiCl_4$ is production of fumed silica, but other applications, include (1) synthesis of silicon esters, (2) production of special glass for the electronics industry, and (3) production of high-purity silicon.

Trichlorosilane [*10025-78-2*], $SiHCl_3$, is made by passing hydrogen chloride through silicon powder at a moderate temperature (280 – 300 °C):

$$2\,Si + 6\,HCl \longrightarrow 2\,SiHCl_3 + 2\,H_2$$

The manufacturing equipment used in this process is similar to that for the production of silicon tetrachloride.

The major application for trichlorosilane is as a raw material for producing high-purity polycrystalline silicon, which eventually becomes the polished silicon wafers used in semiconductor production.

Dichlorosilane [*4109-96-0*], SiH_2Cl_2, is a byproduct in the manufacture of trichlorosilane:

$$Si + 2\,HCl \rightarrow SiH_2Cl_2$$

The only significant application for dichlorosilane is as a source of polycrystalline silicon and silicon nitride for epitaxial deposition in the manufacture of semiconductors. However, Hemlock Semiconductor is conducting experiments using dichlorosilane as a raw material for large-scale production of high-purity polycrystalline silicon.

Silane [*7803-62-5*], SiH_4, is produced by combining an ether solution of silicon tetrachloride with an ether solution of lithium aluminum hydride, as shown in the following equation:

$$SiCl_4 + LiAlH_4 \longrightarrow SiH_4 + LiCl + AlCl_3$$

Silane is used largely as a raw material to form other silicon-containing compounds, but it also serves as a source of silicon for deposition of epitaxial layers.

Types and Grades. The four silicon products are all sold as compressed gases. Purity levels of the gases vary among suppliers, but all are available as semiconductor-grade material (> 99 % pure). The SEMI specification for silicon tetrachloride and for silane (for both polysilium – silicon dioxide and silicon nitride applications) are available [5].

Uses and Toxicology. All four of the silicon gases can serve as a source for epitaxial silicon and silicon dioxide by chemical vapor deposition. Silane forms silicon by simple pyrolysis at temperatures of 800 – 1000 °C, as follows:

$$SiH_4 \rightarrow Si + 2\,H_2$$

The other gases form silicon deposits by hydrolysis and release of hydrogen chloride. Silicon tetrachloride requires a temperature > 1200 °C. The reactions are as follows:

$$SiCl_4 + 2\,H_2 \longrightarrow Si + 4\,HCl$$

$$SiHCl_3 + H_2 \longrightarrow Si + 3\,HCl$$

$$SiH_2Cl_2 \longrightarrow Si + 2\,HCl$$

Epitaxial silicon dioxide layers are formed by oxidation of silane; the other gases hydrolyze in a moist atmosphere. Reactions for these processes are as follows:

$$SiH_4 + O_2 \longrightarrow SiO_2 + 2\,H_2$$

$$SiHCl_3 + 2\,H_2O \longrightarrow SiO_2 + 3\,HCl + H_2$$

$$SiH_2Cl_2 + 2\,H_2O \longrightarrow SiO_2 + 2\,HCl + 2\,H_2$$

$$SiCl_4 + 2\,H_2O \longrightarrow SiO_2 + 4\,HCl$$

Silane and dichlorosilane are also used to form epitaxial silicon nitride deposits for the passivation of semiconductor devices. In each case, the silicon gas reacts with ammonia as the following equations show:

$$3\,SiH_4 + 4\,NH_3 \longrightarrow Si_3N_4 + 12\,H_2$$

$$3\,SiH_2Cl_2 + 4\,NH_3 \longrightarrow Si_3N_4 + 6\,HCl + 6\,H_2$$

Silicon tetrachloride is the easiest of the silicon gases to handle. Although corrosive, it does not ignite on contact with the atmosphere, nor is it classified as toxic. Silicon tetrachloride has the fastest layer growth rates and forms the thickest layers in the deposition of silicon and silicon dioxide, which is important in the manufacture of many linear type devices. It does cause distortion pattern shift in the deposition of epitaxial layers because of the chlorine radicals and requires the highest operating temperatures (> 1200 °C) of all silicon gases.

Silane is considered one of the most dangerous of the silicon gases to handle because it ignites on contact with air. However, the flame is relatively cool and no toxic fumes are known to be released. The ACGIH has established a TLV-TWA of 5 ppm, 7 mg/m^3 (no MAK has been established) [9]. The advantages of silane are that it causes little or no pattern shift during formation of epitaxial layers and that it operates at the lowest temperature (800 – 1000 °C) of all silicon gases. Silane also exhibits a layer growth rate that is the easiest to control. As a result, silane is important in the semiconductor industry as the thickness of epitaxial layers decreases with more sophisticated devices.

Both dichlorosilane and trichlorosilane offer a compromise in characteristics between silane and silicon tetrachloride. Dichloro- and trichlorosilane are corrosive and toxic, but do not ignite when in contact with air. Both cause some pattern shift, but not as much as silicon tetrachloride, and both operate at temperatures between 1100 and 1200 °C. Dichlorosilane is particularly effective in producing thick epitaxial layers and requires less processing time than silane.

Economic Aspects. The total United States consumption of silicon gases for semiconductor fabrication was 108.9 t in 1980. Silicon tetrachloride represented the majority of the volume as shown (in t):

Silicon tetrachloride	45.4
Silane	34
Dichlorosilane	22.7
Trichlorosilane	6.8

The major suppliers of these products in the United States are the Linde Division of Union Carbide, Liquid Carbonic, Matheson, Air Products, Scientific Gas Products, and Synthaton.

10.2. Etchant Gases

Etchant gases are used to remove selected areas of materials such as silicon, silicon dioxide, silicon nitride, glass, aluminum, and tantalum during the processing of semiconductor wafers. The most common gas used for etching is carbon tetrafluoride [*75-73-0*], CF_4, tetrafluoromethane. It is a colorless, nontoxic,

stable gas, which can be used in pure form or mixed with oxygen to etch semiconductor wafers. Other gases that can be used as an etchant include silicon tetrafluoride (SiF_4), fluoroform (CHF_3), hexafluoroethane (C_2F_6), perfluoropropane (C_3F_8), and chlorine (Cl_2).

Types and Grades. Carbon tetrafluoride is sold as a compressed gas. It is usually available with a minimum purity level of 99.7 %.

Uses. The etchant gases are employed in a process known as plasma etching. A plasma resembles a gas, but a fraction of the molecules or atoms are ionized and carry an electrical charge. The plasma also contains a substantial quantity of free radicals, which are electrically neutral but highly reactive. The presence of ions and free radicals makes the plasma very reactive and, thus excellent for an etching process.

A plasma etching system consists of three basic units: (1) a reactor, which holds wafers during etching, (2) a radio-frequency (RF) generator, which supplies energy for creating plasmas inside the reactor, and (3) control equipment for monitoring the etching process. Once the reactor is loaded with wafers, air is evacuated by a mechanical pump. An etchant gas then enters the reactor and is ionized to form an etching plasma. Fresh etchant gas flows into the reactor continuously during etching, while gaseous reaction products are withdrawn from the reactor by a vacuum pump.

The specific etchant gas or gas mixture used for plasma etching depends on the type of material to be processed. Examples of the various etchants that are used are listed in Table 9.

Table 9. Examples of etchants used for plasma etching

Etched material	Substrate material	Gas etchant
Polycrystalline silicon	silicon dioxide	CF_4/O_2 or SiF_4/O_2
Silicon nitride	silicon dioxide	CF_4/O_2 or SiF_4/O_2
Silicon nitride	silicon	SiF_4/O_2
Silicon	sapphire	SiF_4/O_2
Silicon nitride	gold	CF_4/O_2
Tantalum	silicon dioxide	CF_4/O_2
Silicon		CF_4
Silicon dioxide	silicon	CF_4

Economic Aspects. The United States semiconductor industry used 91 000 kg of carbon tetrafluoride as an etchant gas in 1980. An additional 9100 kg of miscellaneous etchant gases, including silicon tetrafluoride, chlorine, hexafluoroethane, and perfluoropropane, was also consumed. The only basic manufacturers of carbon tetrafluoride in the United States are Linde, Air Products, and Du Pont. The Du Pont material is sold through such gas suppliers as Matheson and Scientific Gas Products.

10.3. Light-Emitting Diode Gases

Light-emitting diode (LED) gases are used to deposit epitaxial layers of gallium arsenide, gallium phosphide, and gallium arsenide phosphide onto substrates of the same composition during the manufacture of LED and miscellaneous gallium-based semiconductor devices. Arsine [*7784-42-1*], AsH_3, and phosphine [*7803-51-2*], H_3P, are two gases that are used for this purpose. Both gases are extremely toxic, and exposure to concentrations of 1000 ppm for only a few minutes is lethal. The TLV-TWA and MAK for arsine are 0.05 ppm, 0.2 mg/m^3. For phosphine, the TLV-TWA is 0.3 ppm, 0.4 mg/m^3; the TLV-STEL is 1 ppm, 1 mg/m^3; and the MAK is 0.1 mL/m^3, 0.15 mg/m^3 [9], [10].

Types and Grades. Both gases are available as an LED-grade material, which has purity levels of 99.99 – 99.9995 %. The SEMI specifications for impurities in LED-grade phosphine are available [5].

Uses. Arsine and phosphine are used to form epitaxial devices as LEDs and field-effect transistors (FETs). These gases can also be used as dopants for the manufacture of semiconductor devices (see Chap. 13). Most LED manufacturers utilize the gases in high percentage concentrations, 5 – 10 % for arsine and 5 – 15 % for phosphine, mixed with extremely high-purity hydrogen as the background gas. Some manufacturers have begun to use a pure phosphine gas for growing epitaxial layers, but it is a relatively small percentage of the total demand.

Economic Aspects. In 1980, the United States semiconductor industry used 4500 kg of arsine and 1100 kg of phosphine for manufacturing light-emitting diodes. The most important

supplier of these LED-grade gases is Phoenix Research, now part of Union Carbide.

11. Solvents

Fluorocarbon solvents can be either a fluorinated product or a blend of the fluorochemical with alcohols such as ethanol or 2-propanol. One of the most commonly used materials is 1,1,2-trichlorotrifluoroethane [*76-13-1*], $CCl_2F–CClF_2$, which is a clear, dense, and colorless liquid having a faint solvent odor (→ Fluorine Compounds, Organic).

Manufacturers of semiconductors utilize fluorocarbon solvents to clean wafers; the printed circuit board industry employs these products to remove grease from the boards. In addition, manufacturers of printed circuit boards use fluorocarbon solvents in defluxing operations to remove solder flux after the components are attached.

Isopropyl alcohol [*67-63-0*], $CH_3CHOHCH_3$, 2-propanol, has many chemical and solvent properties similar to those of ethyl alcohol; it has a slight odor resembling a mixture of ethanol and acetone (→ Propanols). Production of isopropyl alcohol is based on the reaction of propene and sulfuric acid to form isopropyl hydrogen sulfate, with subsequent hydrolysis to yield the alcohol and sulfuric acid. Isopropyl alcohol purchased by manufacturers of semiconductors is usually a semigrade product assayed at 99.5 wt % $CH_3CHOHCH_3$.

Manufacturers of semiconductors use isopropyl alcohol to clean wafers; the printed circuit industry also employs this product in cleaning operations.

Acetone [*67-64-1*], CH_3COCH_3, is an inflammable liquid that is low in toxicity compared to other volatile solvents. Acetone is produced by either oxidation of cumene or catalytic dehydrogenation of isopropyl alcohol (→ Acetone). Acetone purchased by manufacturers of semiconductors is often a semigrade product assayed at 99.5 wt % CH_3COCH_3.

The semiconductor industry uses acetone for wafer cleaning, and manufacturers of printed circuit boards use the solvent to clean masks contaminated with dirt.

Trichloroethylene [*79-01-6*], TCE, $ClCH{=}CCl_2$, is a clear, water white, volatile liquid that is completely miscible with most organic solvents, but only slightly soluble in water (→ Chlorinated Hydrocarbons, Chap. 3.4.). The production of TCE is generally accomplished by chlorination of ethylene, forming ethylene dichloride, which is then oxychlorinated to form trichloroethylene. Manufacturers of semiconductors purchase this electronic chemical typically in a semigrade product assayed at 99 wt % TCE.

The semiconductor industry consumes limited quantities of trichloroethylene to clean wafers; however, this industry also uses this product as a chlorination source in crystal growing furnaces, whereby the chlorine minimizes crystal defects. Manufacturers of printed circuit boards use this material in metal cleaning and degreasing operations.

***n*-Butyl acetate** [*123-86-4*], $CH_3COO(CH_2)_3CH_3$, is produced by esterification of acetic acid with *n*-butyl alcohol, using a catalyst, typically sulfuric acid. Manufacturers of semiconductors generally purchase a semigrade product assayed at 99 wt %.

Manufacturers of semiconductors use *n*-butyl acetate as a rinse for negative resists to stop the developing action.

Methanol [*67-56-1*], CH_3OH, methyl alcohol, is produced from steam-re-formed natural gas, which is compressed, catalytically converted to crude methanol, and finally purified by distillation (→ Methanol). Purchases of methanol by the semiconductor industry are typically assayed at 99.9 wt % CH_3OH.

Manufacturers of semiconductors use methanol for wafer cleaning.

1,1,1-Trichloroethane [*71-55-6*], CH_3CCl_3, is one of the least toxic chlorinated hydrocarbons. The most popular route to manufacture this material is from vinyl chloride, which is hydrochlorinated with hydrogen chloride to form 1,1-dichloroethane and then thermally chlorinated to give 1,1,1-trichloroethane (→ Chlorinated Hydrocarbons, Chap. 2.4.).

Semiconductor companies use this electronic chemical for wafer cleaning and in crystal growing furnaces to reduce defects. Manufacturers of printed circuit boards use this material in cleaning operations; however, its more important application in this industry is to develop resists.

Types and Grades. The SEMI specifications for acetone, *n*-butyl acetate, methanol, trichloroethylene, and trichlorotrifluoroethane are available [5].

Economic Aspects. A total of 14.60×10^3 t of solvents was used in the United States for electronic applications in 1980. Of the total, 9.88×10^3 t was used in semiconductor applications and the balance was used in printed circuit boards, as shown in Table 10.

Table 10. Solvents used in printed circuit boards in 1980

Product	Consumption, 10^3 t		
	Semiconductors	Printed circuit boards	Total
Fluorocarbon solvents	0.68	1.13	1.81
Isopropyl alcohol	2.22	0.91	3.13
Trichloroethylene	1.59	0.91	2.50
Acetone	1.72	1.09	2.81
n-Butyl acetate	1.13	0.23	1.36
Methanol	1.81		1.81
1,1,1-Trichloroethane	0.73	0.45	1.18
Total	9.88	4.72	14.60

The major suppliers of semiconductor-grade solvents are Ashland Chemical, General Chemical, J. T. Baker, and Mallinckrodt. There are numerous suppliers of solvents to the printed circuit board industry, including Du Pont, Dow, Shell, Union Carbide, PPG, and Exxon.

12. Masks

Solder Masks. Most solder masks are permanent and are intended to remain on the board; thus, they are usually made of durable scratch-resistant material such as epoxy resins. Temporary solder masks are normally used to protect gold contact fingers from being soldered; the mask can be removed at a later date to expose the gold contacts.

Screening Masks. Screening masks are photosensitive polymeric resins that are screen printed onto a printed circuit board. Once printed, the mask is cured by using either heat or ultraviolet light. After the mask is cured, it acts as a solder resist, selectively protecting the circuitry during component soldering.

Types and Grades. Two types of screening masks are available. One type can be cured thermally, and the other type can be cured with ultraviolet radiation. Both can be either permanent or temporary resists. The masks are supplied as 100 % active material and are ready for use.

Uses. Screening masks are used exclusively by the printed circuit board industry as a solder resist. The mask is applied to the board by forcing it through a stainless steel or polyester monofilament screen. The screen pattern determines where the mask is deposited on the board. Once applied to the board, the mask is cured either by heat or by ultraviolet light. After curing, temporary masks can be removed from the board with hot alkaline solutions of sodium hydroxide and water. Permanent solder masks are not made to be removed after curing.

Economic Aspects. A total of 852×10^3 L of screening masks was consumed by the printed circuit board industry in the United States in 1980. Of this total, ca. 85 % or 719×10^3 L were thermally curing masks. The major suppliers of screening masks in the United States are MacDermid, Photocircuits, Mysol, Colonial, London Chemical, Grace, and Dynachem.

Dry Film Masks. Dry film solder masks consist of a photosensitive polymer layer sandwiched between a layer of polyester film on one side and a polyolefin sheet on the other side. Both cover sheets protect the photopolymer from damage by abrasion. The polyolefin sheet is removed as the solder mask is laminated to the printed circuit board. Ultraviolet light selectively images the mask by polymerizing the exposed photopolymer, causing these areas to be insoluble in the developing solution. The polyester sheet is removed just prior to immersion in the developing solution. After the developing process, the dry film acts as solder resist, protecting the circuitry during component soldering.

Types and Grades. Currently, only two types of dry film masks are available. One type has a heat-resistant coating, and the other has a flame-retardant coating. Both products work negatively and can be processed in solvent, usually with 1,1,1-trichloroethane.

Uses. Dry film masks are used exclusively by the printed circuit board industry and are designed for boards with tight circuitry spacings (≤ 0.3 mm). The developed dry film protects the circuitry from coming in contact with solder when components are assembled on the board.

Economic Aspects. Dry film solder masks were introduced in 1979 by Du Pont. Therefore, consumption of these products in 1980 was low, at 30 480 m^2. Du Pont, Dynachem, and Hercules all offer dry film masks.

13. Dopants

Dopants are materials that enhance the ability of a semiconductor to conduct electricity by selectively forming positively and negatively charged areas within the substrate.

As the dopant contacts the substrate, dopant atoms, such as phosphorus or boron, begin to replace semiconductor atoms, such as silicon, in the crystal structure. Electric charges form because the change of atoms also changes the number of valence electrons that are available in the substrate. Replacing a silicon atom, which has four valence electrons, with a boron atom, which has only three valence electrons, produces a positively charged area because of the absence of one electron. Conversely, replacing a silicon atom with a phosphorus atom, which has five valence electrons, produces a negatively charged area because of an excess of one electron. This imbalance of electrons allows better conduction of electricity through the semiconductor material.

13.1. Liquid Dopants

Liquid dopants are compounds that contact semiconductor substrates to produce charged areas. These liquids include compounds that are liquid at room temperature and solid compounds that are dissolved in solvents to form solutions. The main difference between the two is the method of application. The dopant – solvent solutions are applied by spin-on techniques, while the pure liquids are applied by chemical vapor deposition (CVD) techniques.

Orginally, all liquid dopants were formulated for application by *CVD techniques.* This technique uses a carrier gas, usually nitrogen, which bubbles through the liquid dopant and carries the dopant vapor mixture into a furnace, where the dopant diffuses into the wafer.

Later, *spin-on techniques* were developed. This method uses several drops of the dopant solution, which is placed directly on the wafer, spun to a uniform thickness, and dried to form a dopant film. Once dry, the wafers are placed in a furnace operating between 1100 and 1300 °C, where the diffusion process occurs.

Types and Grades. The two major classifications of liquid dopants are inorganic- and organometallic-based compounds. Within the *inorganic class,* the four main types of doping compounds are based on phosphorus, boron, antimony, or arsenic. The most common inorganic liquid dopants, with the method of application and available purity grades, are shown in Table 11.

The *organometallic dopants* consist of compounds such as diethylzinc, dimethylcadmium, diethyltelluride, and trimethylgallium. These products are available as electronic-grade materials that have a purity in excess of 99.9 % and are formulated for use by CVD techniques.

Uses. The spin-on type of liquid dopants are formulated into several different products by varying the dopant concentration of the solution. These variations cause different concentrations of dopant atoms per unit area in the semiconductor substrate.

Phosphorus, antimony, and arsenic compounds are examples of dopants that produce negatively charged sites (*n*-type dopant); boron, aluminum, indium, and gallium compounds are examples of dopants that produce positively charged sites (*p*-type dopant).

Table 11. Most common inorganic liquid dopants

Product	CAS registry number	Formula	Method of application	Purity grades, wt %
Phosphorus oxychloride	[*10025-87-3*]	$POCl_3$	CVD *	99.995, 99.999, 99.9999
Phosphorus tribromide	[*7789-60-8*]	PBr_3	CVD *	99.995, 99.9999
Phosphorus pentaoxide	[*1314-56–3*]	P_2O_5	spin-on	99.99
Boron tribromide	[*10294-33-4*]	BBr_3	CVD *	99.99, 99.995, 99.999, 99.9999
Antimony trioxide	[*1309-64-4*]	Sb_2O_3	spin-on	99.99
Arsenic trioxide	[*1327-53-3*]	As_2O_3	spin-on	99.99
Antimony trichloride	[*10025-91-9*]	$SbCl_3$	CVD *	99.995, 99.9999

* Chemical vapor deposition.

Economic Aspects. In 1980, almost 6300 kg of liquid dopants was consumed in the United States for semiconductor fabrication. Of this total, ca. 2300 kg was supplied as CVD dopants and the remainder as spin-on dopants. The two leading suppliers of CVD dopants are J. C. Schumacher, now part of Air Products, and Apache Chemical, now part of Olin-Hunt. The important suppliers of spin-on dopants are Emulstone, Diffusion Technology, and General Chemical.

13.2. Gas Dopants

The three primary doping gases are arsine [*7784-42-1*], AsH_3; diborane [*19287-45-7*], B_2H_6; and phosphine [*7803-51-2*], H_3P. All three are colorless, highly toxic, and flammable.

Traditionally, the gas mixture is pumped into a furnace operating at a temperature between 900 and 1300 °C and is introduced into the substrate by diffusion. A newer technique, called ion implantation, operates at room temperature and is gaining popularity for doping of the semiconductor substrate.

Types and Grades. An electronic grade of dopant is used, requiring a minimum of 99.995 % purity. Gas dopants are typically mixed, usually with nitrogen as the carrier gas, although 100 % phosphine is sometimes used. The concentration of dopant gas in the mixture ranges from 5 to 50 000 ppm with the exception of diborane, whose concentration only ranges from 5 to 10 000 ppm. The SEMI specifications for electronic-grade arsine and phosphine are available [5].

Uses. Dopant gases are used to produce selectively charged areas within the semiconductor substrate and within such epitaxial layers as polysilicon and silicon nitride. Arsine and phosphine are examples of dopants that produce negatively charged sites (*n*-type dopant); diborane is an example of a dopant that produces positively charged sites (*p*-type dopant).

Economic Aspects. The total consumption of gas dopants in the United States for semiconductor fabrication was 2300 kg as 100 % active material in 1980. The four largest suppliers of these products in the United States are Matheson, Linde, Scientific Gas Products, and Air Products.

13.3. Solid Dopants

Solid dopants, either in crystalline, powder, or wafer form, contact semiconductor substrates to produce positively or negatively charged sites. Usually these dopants are compounds of metals such as arsenic, antimony, boron, and phosphorus.

Types and Grades. The two main types of solid dopants are boron and phosphorus compounds. These materials are available in grades varying in purity from 99.9 to 99.999 % and are ready for immediate use.

Uses. The boron compounds are examples of dopants that produce positively charged sites (*p*-type dopant) and the arsenic, antimony, and phosphorus compounds are examples of dopants that produce negatively charged sites (*n*-type dopants).

Crystalline or powder-type solid dopants are sublimed and pumped into the diffusion reactor, where the material diffuses into the semiconductor substrate, doping the desired areas. Most boron solids, particularly boron nitride, are available in wafer form and are placed inside the diffusion reactor beside the semiconductor substrate. The boron sublimes and travels a relatively short distance to contact the substrate. Ion implantation may eventually be an alternate application method, and some semiconductor device manufacturers are experimenting with this process.

Economic Aspects. In 1980, ca. 860 kg of solid dopants were consumed by the United States semiconductor industry. Mallinckrodt is the leading supplier for the phosphorus, arsenic, and antimony compounds, and Carborundum is the leading supplier of boron nitride.

14. Auxiliary Materials

A host of auxiliary materials, including ceramic substrates for thick- and thin-film circuits, liquid crystals, conductive inks and pastes, high-purity metals, wafer cleaners, and passivation materials, are used in the manufacture of electronic devices.

14.1. Ceramic Substrates

Ceramic substrates of high-purity alumina (Al_2O_3) are used as the base material in the manufacture of thick- and thin-film circuits (→ Ceramics, Electronic). The alumina content of substrates used for thick films ranges from 94 to 96 %; most thin-film circuits use ceramics having an alumina content of > 99 %.

Because most thick- and thin-film circuits are designed for specific purposes, the shape and size of the ceramic base is made to meet consumer specifications. Consumers are typically semiconductor manufacturers that use thick- and thin-film circuits for resistor networks and hybrid circuits, thus augmenting the capabilities of the semiconductor devices.

14.2. Liquid Crystals

Liquid crystals are used in conjunction with semiconductor devices in applications such as watches, calculators, and electronic games (→ Display Technology). Although not a semiconductor device, the liquid crystal serves as a display or read-out that rivals the light-emitting diode, which is a semiconductor device. The liquid crystal operates by applying an electric charge, which changes the molecular orientation of the liquid. Light passing through the crystal is scattered or reflected where the charge is applied, thereby forming the display. This process allows very little current consumption by the liquid crystal display, which is its main advantage over the light-emitting diode.

14.3. Conductive Inks and Pastes

Conductive inks and pastes are screened onto a ceramic substrate to form the conductors, resistors, and capacitors in thick-film circuits. Thick-film conductors are made from precious metal pastes or inks, such as gold, silver, platinum, and palladium, either separately or in combination. Resistors and capacitors use pastes that consist of glass dielectric materials and metal or semiconducting compounds. The pastes and inks are deposited on the substrate by a stencil screen process and are then fired in a furnace, where the composition of the material determines the final characteristics of the circuit. Other components, such as integrated circuits or discrete semiconductor devices, can be added to the thick-film assembly to form a hybrid circuit device.

14.4. High-Purity Metals

High-purity metals have applications with both semiconductor devices and thin-film hybrid circuits. Aluminum and aluminum alloys (mainly tantalum) are used exclusively to form metallized areas on integrated circuit devices. Precious metals, such as palladium and platinum, are used to form conductive paths in thin-film hybrid circuits. All the metals used have purity levels ranging from 99.9999 to 99.99999 %.

The two methods for depositing the metal onto the substrate are sputtering and evaporation. *Evaporation* is the simpler technique and

involves placing the substrate and the metal source in a ball jar under vacuum. The metal is vaporized by heat and then moves in all directions within the chamber and deposits on the substrate.

Sputtering uses the metal source as a cathode target, which is bombarded by ions of an inert gas. This causes the metal to be deposited on the substrate surface.

14.5. Passivation Materials

Passivation materials protect the finished semiconductor device from damage by environmental factors such as dust, humidity, and temperature. The passivator is applied as the final layer on the semiconductor device. Several types of materials can be used to form passivation layers, such as silicon nitride formed by the reaction of silane and ammonia gases, and polyimide coatings. Only the polyimide material is discussed in this section; the previously mentioned gases are covered in Chapter 10.

The polyimide material is sold as a polyamic acid solution, which is converted by heat to a stable polyimide coating. The material can be applied to the wafer by screening, spraying, dipping, or a spin-on method. The polyimide forms a tough, temperature-resistant coating without pin holes and seems to have an advantage over silicon nitride with devices having many stepped layers. In addition, the polyimide can be used with a photoresist to expose metallized contact areas on the device while the polyimide protects the rest of the chip.

14.6. Wafer Cleaners

Wafer cleaners can be hydrophilic polymers or surfactant materials that are either sprayed, dipped, or spun onto the wafers. These materials remove particles from the substrate surface while such cleaners also protect against edge fracturing.

1. Definitions [5], [6], [17], [22], [25], [26]

Emulsions are disperse systems consisting of two (or more) mutually insoluble or sparingly soluble liquids (→ Disperse Systems and Dispersants). The liquid usually present in excess is termed the *closed, continuous,* or *external phase*, while the liquid dispersed in it is termed the *internal* or *dispersed phase*. If the degree of dispersion is so high that the particles have colloidal dimensions, the term "phase" should no longer be applied to the particles.

The preparation of an emulsion is termed *emulsification* and the agents used for this purpose are termed *emulsifiers* In addition to the emulsifiers, other agents, such as *emulsion promoters* or *stabilizers* are often added to an emulsion to boost the emulsifying process, for example, by increasing the viscosity or providing a protective colloid action.

If the external phase consists of water and the internal phase of an organic liquid, e.g., mineral oil, the term *"oil-in-water"* (o/w) emulsion is used. On the other hand, if water is finely dispersed in a nonaqueous liquid, a *"water-in-oil"* (w/o) emulsion is produced. International abbreviations are being introduced, L – H for an o/w emulsion and H – L for a w/o emulsion, L and H being derived from the Greek "lipos" and "hygros" [39] (Fig. 1). If two nonaqueous liquids, e.g., ethylene glycol in a liquid polyether, are emulsified, the term *"oil-in-oil"* emulsions, abbreviated to o/o emulsion, is used. If two aqueous phases are emusified in each other, they are described as w/w emulsions (see Section 4.2.3).

Figure 1. Types of emulsion in aqueous systems [5, p. 173]

For example, cow's milk is an o/w emulsion consisting of ca. 3.5 % fat dispersed in the aqueous phase. On the other hand, butter is a w/o emulsion containing up to 20 % water in the dispersion.

The formation of a natural emulsion in cow's milk, for example, results in an optimum dispersion and dilution of the nutrients necessary for feeding newborns. In an analogous manner, emulsions are prepared industrially to improve the effect of an active substance in a particular application by using it in a more or less finely dispersed form, or to achieve a convenient method of controlling chemical reactions such as, for example, chlorination or polymerization reactions. In such cases the external phase assumes the role of a transporting and/or diluting agent. Thus, in crop protection, for example, it is usually necessary to produce the active substances in diluted form as an emulsion or a suspension.

The terms *multiple-phase* or *polyphase emulsions* are used to describe systems in which water droplets are already dispersed in the oil droplets of an o/w emulsion (w/o/w emulsion) or systems in which oil droplets are dispersed in the water droplets in a w/o emulsion (o/w/o emulsion). The preparation sequence should be denoted by indices [40]. This, a $w_1/o/w_2$ emulsion is made by dispersing a w/o emulsion in water (Fig. 2).

Figure 2. Polyphase emulsion [5, p. 175]

The term *microemulsion* [1], [3, p. 287], [41–43] is now used to describe an isotropic liquid phase with a specific microstructure that is formed spontaneously [44], [45] and in which the particle diameter is less than 10^{-8} m. These are usually intermediate states between micellar solutions and mesomorphic structures.

The term *atypical emulsion* is used if the emulsifier is no longer free to move in highly viscous systems but is more or less fixed crystallographically, usually as liquid crystals [46].

The term *spontaneous emulsion* is used to describe emulsions that can be formed without supplying substantial amounts of mechanical energy (mean particle diameter 10^{-7} m). These are primarily required in crop protection [47], [48]. For further definitions, see → Disperse Systems and Dispersants.

Solubilization. By *hydrotropy* or *solubility promotion,* a phenomenon is meant that involves a substance being rendered soluble in a pure solvent in which it is sparingly soluble by the addition of another substance. If this third substance is a surface-active compound, the term *solubilization* is used, because the sparingly soluble substances dissolve more easily in the surfactant micelles than in the aqueous solution of individual surfactant molecules [49].

In the case of aromatic or colored substances, it is easy to follow the solubilization process by spectrophotometry (Fig. 3).

Figure 3. Solubilization of Resolin Brilliant Orange RS in water (500 mg/L) by emulsifier PV-15, a polyethoxylated condensed phenol [50], [51]
In order of increasing emulsifier concentration (g/L): a) Without; b) 0.1; c) 1; d) 5; e) 10; f) 20; g) 30; h) 50; i) 100

In the case of emulsions, solubilization becomes involved if the emulsifier is added to the system in a concentration that is greater than the critical concentration for micelle formation [52], [53].

2. Properties of Emulsions

2.1. Droplet Formation

An emulsion is generally imagined to be a milky, turbid liquid such as the familiar cow's milk or rubber latex. However, this milky and turbid appearance arises only in the case of a fairly coarse dispersion of the particles in the external phase (mean particle diameter 10^{-4} – 10^{-6} m). Emulsions with a mean particle diameter of 10^{-6} – 10^{-8} m have the typical appearance of colloidal solutions and exhibit the Tyndall effect [54, p. 176]. If the particles are smaller than 10^{-8} m, the emulsion is highly disperse and begins the transition to a micellar or true solution.

The color of the emulsion often gives a rough indication of the particle size. If the difference in refractive indices of the emulsified components is large enough, emulsions with a bluish appearance are usually more finely dispersed than those with a yellow or reddish appearance.

The particle size of most emulsions is not uniform. If the droplet size exhibits a wide statistical distribution, the emulsion is described as *polydisperse,* in contrast to *monodisperse* systems with a uniform droplet size [55] (→ Disperse Systems and Dispersants). The ideal particle size depends on the availably methods of preparation and industrial application in each case. Most emulsions prepared industrially are polydisperse.

2.2. Enveloping of the Droplet Surface

To prevent droplets from reuniting once they have been formed, energy barriers must be erected that either prevent the droplets from colliding or from fusing if they do collide. The barriers are erected by adding emulsifiers and can be maintained by adding stabilizers.

The polar emulsifier molecules accumulate at the interface between the external and internal phases so that their hydrophilic groups project into the water and their hydrophobic groups project into the organic phase. This produces an interface film, which becomes more extensive and adsorbs additional emulsifier molecules if the droplets are broken up mechanically, until all the droplets are enveloped by a surface film [56]. In the case of an o/w emulsion, the hydrophobic hydrocarbon chains are contained in

the internal dispersed phase (Fig. 4 A), whereas in the case of a w/o emulsion, they project into the external continuous phase (Fig. 4 B).

Figure 4. Envelopment of droplets with a surface film of emulsifier in an o/w emulsion (A) and a w/o emulsion (B)

The thickness of the adsorption layer surrounding the droplets of the emulsion depends on the system and the concentration of the ingredients. Only a few emulsifiers or emulsion promoters can be expected to result in a monomolecular boundary layer, and as a rule, multilayers are built up. Liquid – crystalline boundary layers may be produced with such thickness that the layers become microscopically visible. For information on the calculation of the equilibrium thickness of adhering and free lamellae, see Derjaguin [57], [58] and Frenkel [59].

2.3. Electrical Charge of Emulsion Droplets

In addition to the size of the droplets, the electrical charge of the droplets plays a decisive role in emulsification and stabilization processes (see Section 4.1).

2.4. Interfacial Tension

The accumulation of an emulsifier or an emulsion promoter at the interface between the internal and external phase results in a decrease of interfacial tension between the phases. Thus, the interfacial tension between paraffin oil and water normally is 38.7 mN/m, but after the addition of oleyl decaglycol ether (2 g/L), this tension drops to 5.2 mN/m (for further formation, see Section 3.4).

2.5. Stability [3, p. 129], [11, p. 76],[17, p. 522]

An emulsion is stable if fusion of the droplets is prevented by a sufficiently high energy barrier. In general, the energy barrier is built up by the film of emulsifier that forms at the surface of the droplets. In the absence of an emulsifier, triboelectric charging is probably the only stabilizing factor.

A maximally stable emulsion, however, is not always desirable; its stability should match its application. Thus, for a number of applications, the emulsion should be stable under very specific conditions, but it should then disintegrate into its components (break) after its purpose has been achieved.

Most of the emulsions used in the *textile industry* are designed to have an optimum effect at a particular temperature, at a particular pH, or at a particular concentration of dyes, salts, or the like. Thus, in waterproofing textile materials such as rain coats or tarpaulins, for example, the water-repellent finish is usually applied as an aqueous emulsion. This guarantees a uniform wetting and soaking of the fiber material and, consequently, a uniform application of the waterproofing agent to the fiber. The water subsequently must be removed from the textile material by drying. Breaking the emulsion at as low a temperature as possible facilitates the drying considerably.

Medicines are now increasingly supplied as emulsion concentrates. Among other things, this method of preparation enables the dispensing of dosages of sparingly soluble products to be improved. However, to achieve a rapid absorption of the drug, the retention of the active substance by emulsifiers should not be excessive. Breaking

of the emulsions, for example, by a change in the pH in the intestine causes the desired result.

In *crop protection* and in *pest control,* emulsion concentrates are used in fields, gardens, or greenhouses after dilution with water to form spray mixtures. Since complicated emulsifying equipment is not usually available, emulsifier mixtures, which facilitate spontaneous dispersion of the active substance in water and guarantee uniform distribution of the active substance over large areas, are often used. However, the stability of the spray mixtures should not be high, since they must not be kept for a long time. On the other hand, the emulsion concentrate that is delivered must be stable for some period of time.

Further requirements are very often imposed on the stability of industrial emulsions. For example, they should be stable to storage, heat and/or cold, and in some cases, they should be insensitive to the addition of acids, bases, and/or salts [60]. The production of a stable emulsion depends also on the rate at which the emulsifiers or emulsion promoters that are added diffuse to the freshly formed interfaces and become distributed and concentrated in them.

2.6. Sedimentation and Coalescence

The uniform dispersion of the droplets in the external phase may be destroyed reversibly by sedimentation or irreversibly by coalescence.

Sedimentation. In sedimentation, the uniform dispersion of the droplets is disturbed by aggregation, which leads to *settling* or *creaming* of the internal phase. To keep an emulsion stable, such aggregation must be prevented since droplet aggregates sediment faster than individual small droplets. Sedimentation is not always necessarily accompanied by coalescence (see next paragraph). Although the distribution has been altered, the original dispersion can be restored by shaking or stirring. Often such reversible sedimentation in an emulsion cannot be prevented; however, it is not necessarily troublesome.

Coalescence. In coalescence, the individual droplets fuse together. First, the smaller droplets are absorbed by the larger droplets, and then increasingly larger drops merge together until two continuous phases are finally formed. Two droplets can only coalesce if the intervening layer of liquid is pierced when they approach each other. Therefore, coalescence is opposed in two ways by the emulsifier film surrounding the droplets. First, as in the case of aggregation, the like charges of the electrical double layer prevent them from approaching each other. Second, the buildup of an elastic surface film causes the emulsion droplets to bounce off each other when they collide [61]. Coalescence is always followed by accelerated settling or creaming, which destroys the emulsion completely. The emulsion is then broken and cannot be reconstituted by shaking or stirring.

2.7. Phase Volume Ratio

The ratio of the volume of the internal phase V_i to the volume of the external phase V_e is called the *phase volume ratio* Φ:

$$\Phi = \frac{V_i}{V_e} \tag{1}$$

The corresponding ratio of masses is called the *phase mass ratio.* If $\Phi < 0.43$ ($V_i = 30$ % of total volume), the flow properties of the emulsion are determined primarily by the external phase. If $\Phi > 0.43$, the viscosity of the emulsion generally increases. As Φ increases, either phase reversal or cream formation occurs. A phase volume ratio of ca. 1.1 ($V_i = 52$ % of total volume) corresponds to a body-centered cubic (bcc) packing of spheres, one of ca. 1.8 ($V_i = 64$ % of total volume) to face-centered cubic (fcc) packing of spheres. At phase volume ratio of 2.6 ($V_i = 72$ % of total volume) the packing of spheres is hexagonal and maximum space filling is achieved [62], [10, vol. I].

2.8. Emulsion Type

Whether a w/o or an o/w emulsion is formed depends essentially on the stability of the emulsifier layer surrounding the droplets. If a water-stable emulsifier envelope is formed around the oil droplets in a system containing water, oil, and emulsifier, an o/w emulsion is produced. On the

other hand, the formation of an oil-stable envelope around the water droplets produces a w/o emulsion. The rate at which the droplets coalesce is the determining factor [63]. If the water droplets coalesce more rapidly than the oil droplets, an o/w emulsion is formed, and vice versa [64].

The selection of suitable emulsifiers is specially important in producing an emulsion of the required type. For the solubility of the emulsifier in the internal and external phases (Bancroft rule), see Section 9.1. DAVIES links the emulsion type that is formed with the HLB (hydrophilic – lipophilic balance) values (see Section 9.2). Emulsifiers with a fairly low HLB value form w/o emulsions, and those with a high HLB value tend to form o/w emulsions. Emulsifiers with a moderate HLB value have an equal tendency to form both types of emulsion [63].

The phase volume ratio may also affect the emulsion type. In aqueous systems, an excess of water favors the formation of an o/w emulsion, while a water deficiency favors a w/o emulsion. Moreover, interface films carrying a weak electric charge tend to form w/o emulsions, while o/w emulsions occur with highly charged films [65], [66]. In the phase diagram [36, p. 125], the o/w, and w/o emulsion regions are separated by a line with a constant water – emulsifier ratio [67].

The assumption that a given emulsifier can only form one type of emulsion is inadmissible [12, p. 327]. Although this basic tendency certainly exists, it is affected by the composition of the system, by the phase volume ratio, by the sequence in which the components are added, by the temperature, and by mechanical factors. If mixtures of emulsifiers are used, their mixing ratio may determine the type of emulsion, especially if emulsifiers with opposing tendencies (opposing HLB values) are combined.

2.9. Phase Reversal

The conversion of a w/o emulsion into an o/w emulsion, or vice versa, is called phase reversal. It may occur if the amount of internal phase of an emulsion is increased. However, the emulsion must not be broken in this process, which can be achieved by selecting a suitable emulsifier system. Phase reversal can be achieved relatively easily with a mixture of a water-soluble and an oil-soluble component. The phase reversal is linked to the solubility of the emulsifiers in the two phases [68].

If, for example, a mixture of 2 g of calcium alkyl benzenesulfonate and 3 g of a highly ethoxylated condensed phenol is dissolved in 50 cm^3 of xylene, a w/o emulsion is first obtained when water is added. If the mixture is not stirred too rapidly, phase reversal occurs when ca. 300 cm^3 of water has been added. As further water is added, the o/w emulsion is maintained.

Furthermore, phase reversal can be achieved by increasing the charge of a weakly charged w/o emulsion or by discharging a charged surface film in an o/w emulsion [65]. Phase reversal usually leads to the formation of a finely divided stable microemulsion (see page 13 and 5.3.3). Emulsions prepared by phase reversal are sometimes called inverted emulsions.

The formation of hydrate structures with different water contents supplies an explanation of phase reversal. It may occur if a water-soluble emulsifier hydrate loses so much of its water of hydration that an oil-soluble emulsifier or an oil-soluble emulsifier hydrate is formed. On the other hand, if water is added, phase reversal occurs if an emulsifier dissolved in a nonaqueous phase has formed a sufficiently water-soluble hydrate [69], [70]. In polyglycol ether solutions, phase reversal always occurs at the cloud point [71], [72].

Incomplete phase reversal may also result in oil droplets that are emulsified in water but in turn still have droplets of water in their interior, or conversely, water droplets that still contain oil droplets. In this way, so-called *double* or *multiple emulsions* may be prepared [73], [74] (Fig. 2).

2.10. Rheology [3, p. 405]

The consistency of an emulsion may vary considerably. Thus, in the case of o/w emulsions, the viscosity is usually low and hardly distinguishable from that of a true aqueous solution. On the other hand, in w/o emulsions, viscosity often reaches very high values. The emulsions then have a consistency like butter or ointment, which is often the result of liquid – crystalline gel structures [75], [76].

Figure 5. Viscosity of emulsifier – water mixtures at 30 °C (η) vs. emulsifier concentration (emulsifier made by reaction of phenol with styrene and subsequent ethoxylation [51])
Arrows point at ratios of water molecules to oxygen atoms of poly(ethylene oxide) chain.

Figure 6. Viscosity vs. temperature at various concentrations of emulsifier OM-7-g (ethoxylated oleic acid amide) Concentrations in wt %: a) 0.5; b) 1.0; c) 2.0; d) 5.0; e) 6.0; f) 10.0; g) 15.0; h) 25.0

Figures 5 and 6 show viscosity abnormalities that may be significant in relation to the rheological behavior of emulsions. In Figure 5, the viscosity of an emulsion at 30 °C is plotted against its concentration. The two high-viscosity gel phases are the results of structures in which two and four water molecules are localized at every oxygen atom in the polymer chain [69].

Figure 6 is a plot of viscosities against temperature for an ethoxylation product of oleic acid amide (OM-7-g). The transition from spherical to rod-shaped micelles is assumed to be responsible for this anomalous behavior [77]. However, another group of authors make the flocculation of lamellae responsible for this phenomenon; at increased temperature, these lamellae obstruct each other [78].

The preparation of high-viscosity emulsifier structures is essential in the manufacture of creams, but such gel structures are troublesome in some industrial processes such as the transportation of petroleum in pipelines [1, p. 471].

3. Basic Processes in the Preparation of Emulsions

Different basic processes are operative in the preparation and stabilization of an emulsion, and therefore, a distinction should be made between them [79].

3.1. Breaking up to Drops

The preparation of emulsions always involves breaking up the internal phase–a process that is initiated by supplying mechanical or chemical energy. A geometrical series can be used as the simplest approximation for describing the size reduction of drops. The number of droplets Z_n after n divisions is then

$$Z_n = 2^n \tag{2}$$

Thus, ca. 2.4×10^{15} droplets with a total surface area of ca. 300 m^2 are produced, for example, in emulsifying 10 cm^3 of olive oil as droplets with a radius of 10^{-5} cm. This requires ca. 50 divisions.

If droplet division takes place according to a geometrical series, a monodisperse system is always approached. The polydisperse systems encountered as a rule in practice are due to the formation of smaller fragments, so-called secondary droplets, produced in addition to the large primary droplets in the course of droplet disintegration.

3.2. Increase in Surface Area

When an emulsion is formed, the interface between the phases is considerably increased as a result of the droplets formation. This is clearly illustrated by the emulsification of olive oil. As the disintegration of the phase to be emulsified continues, the interfaces determine the flow behavior of the emulsion and, consequently, the action of the emulsifiers at the droplets surface acquires a decisive importance.

3.3. Work of Division

The liquid always tends to reduce its surface or interface to a minimum; therefore, an increase in interface is possible only if energy is supplied. The work that must be expended on drop division is

$$dA = \mu dI \tag{3}$$

The work dA to be expended is proportional to the increase dI in interface. The proportionality factor is the interfacial tension μ between the phases to be emulsified. Thus, if the interfacial tension between the two phases is high, considerable mechanical energy is required for emulsification unless an emulsifier is added; if the interfacial tension is low, little mechanical energy is consumed.

3.4. Decreasing the Interfacial Tension

[5, p. 180]

The interfacial tension is decreased by adding emulsifiers. In a given two-phase system, an emulsifier is the more effective as it more rapidly decreases the interfacial tension at the lowest possible concentration. To achieve this, the emulsifier molecules must (1) reach the interface from the phase in which they are dissolved as fast as possible (diffusion effect) and (2) be absorbed at the interface (adsorption effect) to decrease the interfacial tension as much as possible. In Figure 7, the interfacial tension between xylene and water is plotted against time. The emulsifier PV-15 has the more beneficial effect in this case, since it decreases the interfacial tension much more rapidly than the emulsifier NP-10.

Figure 7. Interfacial tension μ between water and xylene as a function of time. Emulsifier concentration 0.01 g/L [6, p. 180]
a) Emulsifier NP-10; b) Emulsifier PV-15 [51]

Figure 8 is a plot of the interfacial tension between xylene and water after equilibrium has been reached (after 50 min for emulsifier NP-10 and after 12 min for emulsifier PV-15 in Figure 8) against emulsifier concentration. With the better emulsifier PV-15, low values of interfacial tension are achieved even at a concentration of 0.1 g/L. The poorer emulsifier NP-10 requires a concentration of 100 g/L for this purpose [6].

Figure 8. Interfacial tension μ between water and xylene with and without emulsifiers added at 20 °C [6, p. 181]
a) Emulsifier NP-10 dissolved in water; b) Emulsifier PV-15 dissolved in water or in xylene

The decrease of the interfacial tension is due to the accumulation of the emulsifier molecules at the interface between the phases to be emulsified. The area required by an emulsifier molecule in the interfacial film can be calculated from plots of μ vs. log c, as in Figure 8 using the Gibbs equation, which is [70], [81] as follows:

$$\tau = \frac{1}{RT} \cdot \frac{\mathrm{d}\mu}{\mathrm{dln}c} \tag{4}$$

where τ is the interface adsorption or accumulation in mol/cm^2, R the gas constant, and T the absolute temperature.

The area required, A (in m^2), can then be determined by using Avogadros number, N_A, from τ:

$$A = \frac{10^{-4}}{\tau \cdot N_\mathrm{L}} \tag{5}$$

A molecule of emulsifier PV-15 occupies an area of 88×10^{-20} m^2 (88 Å^2) in the interfacial film, whereas a molecule of emulsifier NP-10 occupies an area of 182×10^{-20} m^2 (128 Å^2). Therefore, the molecules of good emulsifiers only require a small area in the interface. The molecules arrange themselves at right angles to the interface and form a stable film between the phases whose structure is such that the hydrophobic hydrocarbon portions are tightly arranged in the oil phase, whereas the polar hydrophilic emulsifier groups project into the water phase. This structure of the interfacial film has been confirmed by measurements of interfacial tension. Different μ values are obtained, depending on whether the interface is approached from the water phase or from the oil phase [82]. From its importance, it appears correct to regard the boundary layer in an emulsifier system as a third phase.

3.5. Other Factors Governing Emulsification

The decrease in interfacial tension between two phases that are to be emulsified is a necessary, but insufficient condition for emulsification. In addition to the diffusion-dependent interface adsorption [49], [83], the following processes occur:

1) Spreading of emulsifier molecules in a freshly formed interface (Marangoni effect)
2) Flow and turbulence effects that occur when a drop is ruptured
3) Life of the droplet itself
4) In the case of polymer emulsifiers or stabilizers, the additional factor of untangling the polymer loops of the polymer molecules adsorbed at the interface [84], [85] (cf. Section 4.2.3).

Marangoni Effect. The spreading of the molecules in a freshly prepared interface is called the Marangoni effect [86–88]. This effect is important in the formation and merging of droplets [89].

If two emulsion droplets are formed from a larger droplet, e.g., by mechanical division or by Brownian motion, the point of rupture is initially free of emulsifier molecules. This causes an interfacial tension gradient to be produced between the occupied droplet surface and the unoccupied droplet surface; this gradient must be stabilized either by adsorption of emulsifier molecules from the solution or from the interior of the droplet at the interface (Fig. 9 A), or by the molecules present in the interface spreading out (Fig. 9 B). This smoothing out takes place more rapidly as the diffusion or spreading rate is larger.

Figure 9. Emulsification mechanisms
A) Interfacial adsorption (diffusion effect); B) Interfacial spreading (Marangoni effect)

The diffusion and spreading rates depend on the steric structure of the emulsifier molecules. Thus, when emulsions are formed, steric effects become important; these effects are described in more detail under → Disperse Systems and Dispersants.

Flow and Turbulence Effects. When a droplet ruptures, flow and turbulence effects occur between the fragments produced; these effects are intensified by the spreading of the molecules already present in the drop surface. These Marangoni flow effects encourage the formation of new droplets and oppose their coalescence.

A Schlieren photograph (Fig. 10) reveals the flow and turbulence effects produced at the toluene – water interface when acetone passes from the toluene phase into the water [90]. When a spontaneous emulsifier passes from xylene into water, in addition to such flow and turbulence effects, large drop deformations also occur that result directly in the disintegration of the drop.

Figure 10. Schlieren photograph of a toluene drop from which acetone is escaping to the surrounding aqueous phase [90]

Life of the Droplet. The life of the droplet not only has a decisive effect on the stability of an emulsion, but it also plays a part in the preparation of an emulsion. If a freshly formed droplet surface is not occupied rapidly enough by emulsifier molecules, they encounter so little resistance while colliding that they coalesce again immediately after being formed. This always occurs if the diffusion, spreading, and absorption rate of the emulsifier molecules are too low. Even if only one of these rates is too slow, adequate emulsification is not achieved.

3.6. Mixed Emulsifiers [91], [92]

If a *nonionic polyglycol ether* is used as an emulsifier, stable o/w emulsions are generally obtained only at a high emulsifier concentration, which ensures the formation of a compact elastic surface film (Fig. 11 A). A reduction in emulsifier concentration can be achieved if two nonionic components that have markedly different HLB values are used [93].

Figure 11. Action of mixed emulsifiers
A) Nonionic emulsifier, high emulsifier concentration; B) Ionic emulsifier, mutual repulsion of the individual emulsifier molecules; C) Mixed emulsifier, low emulsifier concentration necessary, no repulsion

On the other hand, *ionic emulsifiers* alone do not usually result in usable emulsions, since the like charges on the emulsifier ions prevent the formation of a stable surface film (Fig. 11 B). The ions adsorbed at the interface repel each other despite the fact that they are screened by their hydration envelopes.

However, both of these disadvantages are eliminated if a *mixture of a nonionic and anionic emulsifier* is used. In the ideal case, a film is produced at the interface between the phases in which ionic and nonionic emulsifier molecules alternate (Fig. 11 C) [91]. This combines the desirable elasticity of polyglycol ether films with the stabilizing effect of surface films containing like charges. However, since some of the mutual repulsion of like ions is retained in such films despite screening by the polyglycol ether molecules, the surface film is loosened. In this way, the amount of emulsifier required can be markedly decreased.

In practice, a mixture of 40 – 50 wt % of ionic component and 50 – 60 wt % of nonionic polyglycol ether has proved successful as a mixing ratio. A more precise assessment cannot be made since the interface film equivalents of the individual emulsifiers in the film surrounding the emulsion droplets are unknown.

4. Basic Processes in the Stabilization of Emulsions [79], [94]

4.1. Electric Charge

If an emulsion of two phases is formed mechanically, the triboelectric effects produce a measurable potential difference (zeta potential) between the internal and external phases. In most o/w emulsions, the oil droplets are negatively charged.

When emulsifiers are used, the accumulation of surfactant molecules in the droplet surface results in additional charging or in charge reversal. When ionic emulsifiers are used, this change of charge is particularly large. Anionic emulsifiers intensify the negative charge of oil droplets in an o/w emulsion, whereas cationic emulsifiers initially produce a charge reversal. In any event, like charges are finally produced on the surface of the droplets, which opposes any coalescence. In o/w emulsions, the electrical charge on the droplets is generally greater than that in w/o emulsions.

The charging of the drops is shown diagrammatically in Figure 12. In the solution the emulsifier is dissociated (Fig. 12 A) and the droplet surface of the emulsified oil is first charged negatively by the emulsifier anions. Cations are then attracted from the surfactant solution by the negatively charged droplet surface and bound in accordance with their charge. This produces an electrical double layer, called the Helmholtz layer [95] (Fig. 12 B). This extracts further ions from the electrically neutral solution so that a diffuse ion cloud, also called stern layer, is formed [96] (Fig. 12 C). Under these circumstances, the concentration of positive ions decreases as the distance from the phase boundary increases. The potential difference between mobile droplets and solution is symbolized in Figure 12 C by four electrons; it is called the zeta potential, which can be measured, for example, electrophoretically (see page 40) [97, p. 577], [17, p. 383], and [98].

For the mathematical treatment of electrical absorption forces and their interaction with the van der Waals forces of attraction, using the DLVO theory [99–101], see → Disperse Systems and Dispersants.

4.2. Steric Factors [7]

Electrical forces play a subordinate role in relation to stability in nonpolar or weakly polar media. Therefore, other physical parameters, such as density and viscosity of the internal and external pase, become more important. However, steric factors in particular oppose the van der Waals attractive forces. Thus, the steric factors acquire a dominating role in all w/o emulsions, but they may also be important in o/w emulsions.

4.2.1. Molecular Mobility

In the case of emulsifiers for o/w emulsions, the ability of the ethylene oxide chains to rotate freely impedes the approach of two droplets because this free rotation results in the chains becoming interlocked and additional work is required to overcome this. In a similar manner, hydrocarbon chains protect the water droplets in a w/o emulsion from coalescing.

An increase in the length of the hydrocarbon chains and/or the poly(ethylene oxide) chains makes an emulsion more stable. The mobility of the molecules increases with increasing temperature in the case of this "steric effect"; i.e., the disorder is increased and the term *entropy effect* is also used. This effect can be recognized from the increase in stability with rising temperature.

Viscosity Effect. In general, all of the factors that make droplet movements difficult favor the stability of an emulsion. An increase in viscosity, therefore, promotes emulsion stability. Consequently, the selection of a suitable thickening agent may be decisive for achieving the appropriate stability of an emulsion.

4.2.2. Complex Formation

Hydrate Formation. In emulsions, the solvating envelops have a stabilizing action on the droplet surfaces. Thus, the hydrated groups projecting into the water form a more or less continuous hydrate envelope that opposes any approach between droplets. Emulsifiers that are completely and stably hydrated stabilize an o/w emulsion better than those that have only a few

Figure 12. Charging of the emulsion droplets and generation of the zeta potential (diagrammatic)
A) Formation of the surface film; B) Formation of the Helmholtz electric double layer; C) Formation of the Stern diffuse ion layer (potential gradient perpendicular to interface)

localized water molecules. However, the latter are suitable emulsifiers for w/o systems.

Since hydrogen bonds are loosened or broken up as the temperature rises, the emulsion stability decreases with an increase in temperature, and this effect is referred to as an *enthalpy effect.*

Liquid – Crystalline Phases. In emulsions with a high emulsifier content, the stability is increased by the emergence of liquid – crystalline phases [102], [103] in the external phase [104–107]. The increase in viscosity associated with this also contributes to the improvement in stability [52], [53], [108]. Thus, in the system water –*p*-xylene – 4-isononylphenol-9-glycol ether (NP-9), the addition of even a small amount of emulsifier leads to the formation of stable emulsions as a result of the appearance of a liquid –crystalline phase. In the system water – *n*-hexadecane – NP-9, the stability is substantially less because liquid crystals are not observed [109], [110]. Liquid – crystalline phases often occur as gels in the hydration or solubilization of emulsifiers [111]. A different arrangement of the emulsifier molecules may also lead to such liquid – crystalline phases [64].

Microemulsions. The formation of micellar three-dimensional structures at the phase boundary is responsible for the stability of microemulsions [92]. Since the emulsifiers of these often highly viscous systems cannot move freely but are generally fixed crystallographically, they are also termed atypical emulsions, and in many preparations they have lost the true nature of an emulsion [112].

4.2.3. Polymers in Emulsions [6, p. 459], [113–115]

The chemical structure of polymers makes them particularly suitable for stabilizing emulsions. The essential precondition for steric stabilization is adsorption of macromolecules at the droplet surfaces [116], [117]. In addition to chain segments situated parallel to the phase boundary (trains; c in Fig. 13), tails (a) perpendicular to the boundary and loops (b) are formed in the course of such adsorption [118].

Figure 13. Steric emulsion stabilization by polymers
a) Tails; b) Loops; c) Trains

Figure 13 shows that relatively long tails, in particular, are responsible for steric stabilization. This phenomenon occurs in the following way: if droplets approach each other, the free mobility of the tails is restricted, and the entropy is reduced while the free energy increases. This is opposed by the system and the particles repel each other.

On the other hand, if the interfaces are not completely occupied, the tails of the macromolecules may form bridges between the droplets. This may produce *bridging flocculation,* which is promoted by a high degree of polymerization of the polymers and by a low solubility in the external phases (for more details, see → Disperse Systems and Dispersants).

If two polymer layers penetrate each other, the segment density increases and a stronger interaction is produced between the segments. In this case the free energy generally increases; i.e., the particles repel each other. Only when the polymer is sparingly soluble in the external phase is the effect reversed [119].

The manner in which a polymer behaves in an emulsion determines whether it stabilizes the system or destabilizes it. To achieve adsorption, the interaction between polymer and droplet (oil or water) must be high and that between polymer and solvent must be weak so that no desorption occurs in the event of a collision produced by Brownian motion. On the other hand, the interaction between polymer and solvent must be high for steric stabilization to occur. For these reasons, block or graft polymers are especially suitable as emulsions stabilizers. They have segments that are insoluble in the external phase and adhere to the droplets of the internal phase, as well as tails that are soluble in the external phase and produce the stabilization.

Not only can o/w and w/o emulsions be stabilized by such block and graft polymers, but also o/o and w/w emulsions. Thus, a dimlethylformamide – cyclohexane emulsion can be produced, for example, with a polystyrene – polyisoprene block polymer. A w/w emulsion can be obtained with a copolymer of poly(ethylene oxide) and poly(vinylpyridinium chloride) [114]. The w/w emulsions play a role in biological processes and are acquiring increasing significance in bioengineering and pharmacy, e.g., in vesicle formation.

4.3. Further Stability Factors

A rise in *temperature* as a rule opposes stability [120], entropy stabilization being an exception. The difference in *density* between the two phases should be as low as possible, and account should be taken of this factor in selecting suitable solubilizers. In stable emulsions, the droplets should be as small and uniform as possible. A high *zeta potential* should favor stability [121], and the *HLB values* (see Section 11.5) should be adjusted to optimum values [122]. The magnitude of the *dipole moment* of the oil to be emulsified is inversely proportional to the stability of the o/w emulsion [123].

4.4. Long-Term Stability

To ensure the long-term stability of an emulsion, recrystallization of an emulsifier must be prevented or suppressed. Liquid emulsifiers generally result in emulsions with good long-term stability. Complex formation between the emulsifier and the internal or external phase may, however, result in compounds that crystallize even when liquid emulsifiers are used.

Mixtures have proved valuable when crystalline or liquid – crystalline emulsifiers are used, since the melting point is reduced and the tendency to crystallization is repressed. Moreover, the addition of a small amount of solubilizer often performs a valuable service.

4.5. Emulsion Thickening Agents

The emulsion can also be stabilized by modifying the external phase. Emulsion thickening agents increase the viscosity of the external phase, which slows down the motion of the emulsion droplets and counteracts or even prevents any coagulation of the droplets. Since emulsion thickening agents in small concentrations often produce high viscosities in aqueous systems, polymer chains may be assumed to be "cross-linked" by water molecules.

4.6. Cream Formation

Creams or water-containing ointments contain large quantities of water that often exceed 80 %. They are the result of the formation of a lamellar structure by liquid – crystalline hydrate phases, which can in turn store additional water [76], [124]. Therefore, in the creams two different

types of bound water may be encountered, water of hydration and storage water. In the case of water of hydration, the water molecules are attached to the hydrophilic groups of the emulsifiers, and in the case of the storage water [125], the water molecules are stored more or less loosely between the hydrated lamellae.

5. Preparation of Emulsions

Emulsions can be prepared mechanically by using stirrers or emulsifying machines, or chemically by adding emulsifiers.

5.1. Theories Relating to Mechanical Disintegration

In mechanical emulsification, the interface between the two liquid phases is first deformed to such an extent that drops are produced. These drops are usually too large, and must then be broken up into smaller ones.

The mechanical deformation of drops in laminar shear flow was studied by LAMB and TAYLOR as early as 1932 [126]. There are now theoretical hypotheses and experimental studies relating to the disintegration of particles in turbulent flows and in shearing fields [3, p. 57], [127]. The difficulty in arriving at fundamental results is indicated by the work of KOGLIN, PAWLOWSKI, and SCHNÖRING [128].

5.2. Emulsifying Machines [129–131]

In mechanical emulsification, the work necessary to reduce the liquid to droplets and the associated increase in interface area is usually supplied to the system by frictional forces. They are produced by the liquids flowing past each other (shearing) and increase as the relative flow velocities and the viscosity of the system are higher. Contact with solid parts of the equipment reinforces the frictional forces. The following devices are available for mechanically preparing industrial emulsions:

1) High-speed stirrers
2) Agitation or impact machines
3) Emulsifier centrifuges
4) Colloid mills
5) Metering pumps (atomizers)
6) Vibrators
7) Ultrasonic generators
8) Homogenizers

The emulsifying machines under 1 – 4 all seek an ideal mixture of the phases to be dispersed. At the same time, excessively intensive shearing can result in breaking of the emulsions. In the case of *metering pumps*, emulsion formation only occurs above a critical injection rate when injection is carried out with or without pressure [93], [132]; the mean droplet size depends on the injection rate, the size of the nozzle orifice, the interfacial tension, and the viscosities of the two liquids. In *vibrators* the necessary frictional forces are produced by a considerable acceleration of the movements in the liquid that is achieved by cyclic oscillations [133]. Other devices make use of plates attached to rods, which are caused to vibrate by a.c. solenoids or by eccentric motion [13]. In *ultrasonic generators* the emulsifying action of ultrasound is attributed to the cavitation forces generated in the liquid. *Homogenizers* are intended to reduce the size of coarse polydisperse emulsions. To do this, the coarse emulsion is usually forced through narrow jets to minimize the effects of large differences in droplet size. Repeated homogenization initially improves the droplet distribution, but soon leads to a limiting value of the droplet size of ca. 1 – 2 μm [134], [135].

It is often necessary to prepare a preliminary solution of the liquid to be emulsified in a solvent that is miscible with the external phase (e.g., alcohol). When this solution is then stirred into the external phase (e.g., water) or injected through jets, very fine droplets are usually produced with a fairly uniform droplet size, which depends on the concentration of the internal phase in the auxiliary solvent. The general disadvantage of purely mechanical emulsification is that only emulsions of low concentration (0.1 %) can be prepared. To reduce the work involved in emulsification, small quantities of emulsifiers are usually added in most mechanical processes.

Table 1. Nonionic emulsifiers

5.3. Use of Emulsifiers

5.3.1. General Rules

In the vast majority of cases, emulsions are prepared with the aid of one or more emulsifiers, usually with different HLB values. The emulsifier is either dissolved or pre-emulsified in the oil or water phase, and this solution is then worked into the external phase, or the external phase is slowly added to the emulsifier – oil mixture. Phase reversal may be used in this process. The following rules may produce the desired result:

Hydrophilic emulsifiers with a high HLB value favor the formation of o/w emulsions. Thus, hydrophilic alkali-metal soaps are used more often to obtain o/w emulsions than are the sparingly soluble alkaline-earth-metal soaps, which are more suitable emulsifiers for the w/o type. If the hydrophilic emulsifier is sufficiently soluble in the oil phase, the emulsifier should be dissolved in oil and both should be stirred into water. These emulsifiers diffuse rapidly to the interface. The high solubility in water facilitates the insertion of the hydrophilic groups into the water and the formation of a stable interfacial film.

Hydrophobic emulsifiers with a low HLB value are generally more suitable for preparing w/o emulsions. They are accordingly sparingly soluble in water and diffuse rapidly through the interface if they are dissolved in water. Their high solubility in oil results in rapid insertion of the hydrophobic parts of the molecules into the oil phase.

However, in practice the water solubility of oil emulsifiers or the oil solubility of water emulsifiers is often too low. As a result, compromise solutions must often be used. Preparation of the emulsifier may be expedient only at the mixing stage, since its formation results in stable films at the interface. When w/o emulsions are prepared with the aid of aluminum soaps, this method gives outstanding results. For this purpose, the aluminum salt is dissolved in the aqueous phase and the fatty acid in the oil. When the two phases are mixed, the aluminum soap forms at the interface where it is required as an emulsifier.

5.3.2. Preparation of Multiple Emulsions

Multiple emulsions are prepared by first producing a w/o emulsions, using a hydrophobic emulsifier such as sorbitan monooleate, and then mixing this emulsion with an aqueous solution of a hydrophilic emulsifier such as polyethoxylated sorbitan monooleate [136]. An $o_1/w/o_2$ emulsion can similarly be prepared by mixing an o/w emulsion with an oil solution of a hydrophobic emulsifier. A multiple emulsion may also be produced by incomplete phase reversal [137], [138].

5.3.3. Preparation of Microemulsions

As a rule, microemulsions consist of four components: (1) the substance to be emulsified, (2)

Table 2. Anionic emulsifiers

water, (3) the emulsifier or the emulsifier mixture, and (4) a solubilizer [1], [24], [139].

For example, a cloudy emulsion of benzene in an aqueous potassium oleate solution becomes clear when alcohol is added. If short-chain alcohols are used, an o/w emulsion is produced, while alcohols with a chain length of more than six carbon atoms result in the formation of w/o emulsions [140].

Microemulsions containing 5 – 10 % of a suitable solubilizer can be readily prepared, as long as certain conditions are met [141]. If non-

ionic surfactants are used, the solubilizer can be deleted [142].

A microemulsion is believed to consist of very small droplets surrounded by a monomolecular layer of alternating molecules of the emulsifier and the solubilizer [140]. NIKITINA detected three-dimensional micellar structures in microemulsions [92], and ADAMSON conceived microemulsions as expanded micelles [143]. The thermodynamic stability of microemulsions is demonstrated by their representation in phase diagrams [144], [145]. In the preparation of microemulsions, cloudy transitional states with marked birefringence occur and various stages of hydration have been detected in such microemulsions [146].

5.3.4. Spontaneous Emulsification

For the purpose of spontaneous emulsification, emulsion concentrates are prepared that emulsify automatically when they are introduced into water. The movement during mixing is sufficient to produce the emulsion, but occasional stirring is often advisable. The emulsion concentrates usually contain suitable combinations of emulsifiers [147], which reduce the interfacial tension between the phases to be emulsified virtually to 0. The addition of solubilizers such as, e.g., alcohols [67], [148], and/or xylenes is often unavoidable, since spontaneous emulsification takes place more readily as the components to be emulsified are more soluble in each other. In addition, the solvents, which are present often only in small quantities, reduce the viscosity of the interfacial film. Since microemulsions are often produced in spontaneous emulsification, pre-emulsification (by adding a little water to the emulsion concentrates followed by phase reversal) often produces the desired result.

5.3.5. Inorganic Emulsifiers

The emulsifying action of inorganic emulsifiers depends largely on the specific surface area of the solids used. If high-efficiency mixing equipment is employed (e.g., a high-speed stirrer), the solid emulsifier can even be added slowly during the mixing operation [16, Vol. I/2], [79]. Fine grinding is consequently necessary. The resultant powders may be introduced into one of the two phases, into both phases, or into the interface between the phases. Before use, they may be wetted with water or oil.

6. Breaking of Emulsions

Breaking is the term applied to the irreversible coalescense of the individual emulsion droplets to form a continuous phase [5, p. 189], [6, p. 453], [16, Vol. III, p. 213], [62], [149]. To break an emulsion, the stabilizing forces must be weakened or eliminated, and the forces of attraction and the bonding mechanisms between emulsion droplets must be reinforced; see also → Disperse Systems and Dispersants.

Temperature Increase. Breaking of an emulsion is usually favored by an increase in temperature. As the temperature rises, the kinetic energy of the individual droplets is increased. This facilitates coalescence during collisions since the protective envelopes of the droplets are more easily penetrated under these conditions. If an emulsion is stabilized sterically, a rise in temperature may favor stability (see Section 4.2.3.).

Addition of Electrolytes. The addition of electrolytes often causes an emulsion to break, since the electric charge of a boundary layer is very sensitive to the addition of foreign ions. The effectiveness of the added electrolyte increases with its valency. Thus, aluminum or iron sulfate is more effective than sodium sulfate, and the latter is in turn more effective than sodium chloride (Shulze – Hardy rule [14, p. 475]).

Electric Fields. Particular use is made of the discharge of the interfacial film at oppositely charged electrodes for breaking w/o emulsions of crude oil.

Removal or Destruction of Emulsifier. To reduce the stability of the interfacial film, substances are added to the emulsion that displace the film-forming components from the interface. The number of emulsion-breaking substances listed in the literature almost equals the number of emulsifiers, and includes additives that destroy the emulsifier directly. Acids or bases,

for example, destroy hydrolysis-sensitive emulsifiers. The addition of a cationic compound to an emulsion stabilized with an anionic emulsifier usually results in rapid breaking, since sparingly soluble complexes, which precipitate from the system, are produced [150].

Occasionally, adsorption of the emulsifiers on solids is also possible. All the well-known adsorption agents, such as activated carbon, silica gel, and fuller's earth, are suitable for this purpose. This method does not produce any appreciable loss in either phase. Adsorption breaking is particularly suitable for purifying condensation water, e.g., in the removal of trace amounts of oil from the cooling water of power plants.

An emulsion can also be broken by producing a small amount of a voluminous precipitate in the aqueous phase. Iron and aluminum oxide hydrates are particularly suitable for this purpose. For example, iron oxide hydrate may also be produced continuously at the anodes of electrolysis equipment.

Mechanical Stress. An emulsion is often broken by shaking, by impact, or by the action of pressure. Thus, the protein film of the fat droplets in milk is destroyed mechanically in the making of butter. At the same time, foam formation removes some of the proteins from the milk. In road construction, the breaking of the bitumen emulsion is promoted by the application of pressure.

Dilution, Evaporation, and Freezing. Diluting the external phase or concentrating it by evaporation also usually breaks the emulsion. Complete evaporation of the external phase leaves a residue consisting of the internal phase and the emulsifier. If the emulsifiers are thermally stable, the emulsion is reconstituted when the external phase is added again. A porous material may also be used to remove a phase from an emulsion system, as in the seepage of the water from a bitumen emulsion to the gravel bed.

Interaction of Several Factors. To break a stable emulsion, several factors usually must be exploited simultaneously. For example, to break natural rubber latex, the stabilizing protein film is destroyed by the action of heat, addition of acid or alkali, enzymatic degradation, and possibly by addition of fungi or bacteria. In the context of wastewater purification, extensive references to the cracking of industrial emulsions in the detergent, metal-processing, and oil industries, as well as in the food industry and related fields, are given in [151].

7. Chemical Structure of Emulsifiers

Any attempt to classify emulsifiers is made difficult by the fact that the active substances belong to chemically very different categories [6, p. 455]. A helpful distinction is made between surface-active emulsifiers (Table 1, 2, 3, 4), natural substances that are only partially surface-active (Table 5), and inorganic emulsifiers, which generally have low surface activity (Table 6).

Tables 1, 2, 3, 4, 5, 6 summarize the common emulsifiers. In addition to the chemical names, a trade name that has become established throughout the world for an emulsifier type is occasionally cited in quotation marks.

** Biologic degradability.

In the tables the first letter of the identification (ID) classifies emulsifiers as follows:

N	nonionic	surface-active emulsifiers
A	anionic	surface-active emulsifiers
K	cationic	surface-active emulsifiers
M	ampholytic	surface-active emulsifiers
T	natural products	partially surface active
R	inorganic emulsifiers	surface activity generally low

In the structural formulas, the long wiggly lines denote a straight hydrocarbon chain. In most cases, branched chains may also be used. If only derivatives with branched hydrocarbon chains are available commercially, the wiggly lines bear vertical bonds (e.g., last entry in Table 2). If an F appears over the wiggly line (e.g., third entry in Table 2), the chain is perfluorinated. Since only the straight chains are biologically degradable, such products are increasingly important [156], [157].

The information on biologic degradability (BD) relates to compounds with straight hydrocarbon chains [158]:

+	More than 85 % biologically degradable
(+)	Partially degradable; generally the straight hydrocarbon chain is degraded, leaving behind, for example, the polyglycol ether groups, which have virtually no surface activity.
−	Not degradable
(−)	Only degradable in dilute solutions; above a certain threshold level, the mostly cationic emulsifiers have a bacteriostatic action and inhibit any degradation process
(eutro)	Accelerates the growth of algae in rivers and lakes so strongly that the biological equilibrium is disturbed

7.1. Surface-Active Emulsifiers

All surface-active emulsifiers molecules consist of a section that is hydrophobic (lipophilic) and sparingly soluble in the aqueous phase and another section that is hydrophilic (lipophobic) and highly soluble in the aqueous phase [16], [19], [20], [33], [152].

The hydrophobic section of the molecule is always a nonpolar aliphatic and/or aromatic hydrocarbon group, whereas the hydrophilic section contains either an ionic group or an accumulation of OH groups (saccharose derivatives) or of poly(alkylene oxide) groups, e.g., $(-CH_2-CH_2-O-)_n$.

The latter substances lack polar ionic groups and, therefore, are described as nonionic surfactants (Table 1). In the case of polar surfactants, a distinction is between anionic (Table 2) and cationic surfactants (Table 3), depending on whether the main entity that is left behind after dissociation is negatively or positively charged. The term "ampholyte" is applied to an ionic emulsifier that forms zwitterions (Table 4). These emulsifiers may act either as acids or as bases, depending on the pH [108]. All classes of surfactants find extensive use as emulsifiers.

7.2. Natural Products

Most natural products or their derivatives, such as cellulose ether, carboxylic acids, or ligninsulfonate, are emulsion promoters and have little or no surface activity (Table 5). They may be added to the emulsions as protective colloids [153] or to increase the viscosity and, consequently, the stability. Occasionally their object is also to give the emulsion certain mechanical, optical, or electrical properties. Thus, the lecithin and cholesterol content of egg yolk imparts the desired mechanical strength to mayonnaise prepared from it. In contrast to most surface-active synthetic emulsifiers, the natural substances are generally sensitive to changes in temperature and pH [16, p. 126].

7.3. Inorganic Emulsifiers

The chief inorganic emulsifiers are bentonite and fuller's earths, but china clay, activated carbon, or finely ground metal dust may also be used (see also Section 5.3.5). Freshly precipitated basic salts of aluminum, calcium, copper, nickel, or zinc [154], [155] and partially flocculated sols of $Fe(OH)_3$ or $Cr(OH)_3$ have proved very successful as o/w emulsifiers. Solid emulsifiers having a more hydrophobic surface, such as activated carbon, tend to form w/o emulsions. Oxide hydrates of aluminum or suitable heavy-metal salts such as those of zirconium are constituents of emulsions used as waterproofing agents (Table 6).

7.4. Sources of Supply

Emulsifiers are produced by many chemical factories, some of which are listed below (from [15, Vol. 2, p. 197]).

Aceto Chemicals, Flushing, United States
Akzo, Düren, F. R. of Germany
Albright & Drieson, Whitehaven, Great Britain
Armoir, Chicago, United States
Atlas Chemical, Wilmington, United States
BASF, Ludwigshafen, F.R. of Germany
Bayer, Leverkusen, F.R. of Germany
Beacon Chemicals, Cambridge, United States
C. Becker, Hamburg, F.R. of Germany
Carbide & Carbon Chem., New York, United States
Chem. Werke Hüls, Marl, F.R. of Germany
Chem. Y. Bodegrawn, Netherlands
Ciba–Geigy, Basel, Switzerland
Colgate, Jersey City, United States
Comp. Franc. Prod. Industriels, Asnières-sur-Seine, France
Croda, Yorkshire, Great Britain
Dow Chemical, Midland, United States
Drew, Booton, United States
Du Pont, Wilmington, United States
Dutton & Reinisch, London, Great Britain
Dynamit-Nobel, Köln, F.R. of Germany
Eastman Kodak, Rochester, United States
Emery, Mauldin, United States
Emulsion A/S, Palsgaad, Denmark
Emulsol Chem., Chicago, United States
Gilnow, Hamburg, F.R. of Germany
Goldschmidt, Essen, F.R. of Germany
Grünau, Illertissen, F.R. of Germany
Heftl, Zürich, Switzerland
Henkel, Düsseldorf, F.R. of Germany
Hercules Powder, Wilmington, United States

ICI, Manchester, Great Britain
Lion Fat, Tokyo, Japan
Marabishi, Osaka, Japan
National Anilin, New York, United States
Nihon Surfactant, Tokyo, Japan
Ninol, Chicago, United States
Nopco, Moristown, United States
Onyx Chemical Co., Jersey City, United States
Rewo, Steinau, F.R. of Germany
Rohm & Haas, Philadelphia, United States
Shell, London, Great Britain
Stockhausen, Krefeld, F.R. of Germany
Sudfeld, Melle, F.R. of Germany
Tensia, Liège, Belgium
Ugine Kuhlmann, Levallois, France
Unilever, Buurje, Netherlands
VEB Fettchemie, Karl-Marx-Stadt, German Democratic Republic
Witco, London, Great Britain
Zschimmer & Schwarz, Lahnstein, F. R. of Germany

A comprehensive list of manufacturing companies and their addresses can be found in [159]. *"McCutcheon's Functional Materials"* lists commercial products for various fields of application. The 1979 issue does not include products made by European companies. Further sources of supply for emulsifiers are given in [5, pp. 771 –977], [160], [161].

8. Chemical Structure of Emulsion Promoters [6, p. 459]

8.1. Polymers

Polymers of all types are now being used increasingly to stabilize emulsions (Table 7). A number of polymer compounds, for example, certain polyurethanes, are inherently dispersible without requiring any other additive. The interfacial activity of other polymers must be increased by adding emulsifiers and/or emulsion promoters [115, Vol. I, p. 55]. Copolymers are particularly suitable for preparing emulsions and suspensions because the mixing ratio of hydrophilic and hydrophobic components can be matched to almost any particular application [114]. The action of polymers in stabilizing emulsions is described in Section 4.2.3. If a mixture consisting of an emulsifier of low molecular mass and a highly polymerized stabilizer is used, the emulsifier molecules may be adsorbed on the polymer chains and transported by the latter to the interface [162].

Table 7 provides an overview of polymers that are used as emulsion promoters, for example, as stabilizers, as emulsion thickening agents, or as protective colloids.

8.2. Special Emulsion Promoters

In many cases other agents are necessary for preparing, stabilizing, and preserving emul-

sions. Typically, organic solvents are used as *solubilizers.* For example, the spontaneous emulsification of concentrated emulsions of crop protection agents usually requires the addition of a small quantity of an aliphatic alcohol as a solubilizer. The addition of urea and its derivatives, particularly to emulsions of textile or dyeing auxiliaries, is widespread; urea is generally considered to be a solubilizer.

For the *thickening of emulsions*, such natural products as alginates or locust bean gum are used, as well as large quantities of synthetic polymers and copolymers, e.g., styrene and acrylates or butadiene and acrylonitrile [163].

Protective colloids are occasionally added to counteract the coalescence of emulsions once they have been formed. These colloids surround the formed droplets, but unlike the emulsifiers, they do not invade the internal phase. They are added to the external phase, in which they are usually quite soluble, and are intended to keep the emulsifier drops in suspension once they have been formed. Thus, in the copolymerization of styrene and divinyl benzene for preparing ion-exchange resins, poly(vinyl alcohol) is used as an emulsifier and a cellulose ether is used as a protective colloid. Household detergents generally contain carboxymethyl cellulose as a protective colloid to prevent the dirt particles from being readsorbed on the substrate after they have been detached (graying inhibitors).

Biocides. Emulsions are readily attacked and destroyed by bacteria and fungi [164], and the use of biologically degradable emulsifiers promotes such destruction. For this reason, preservatives and disinfectants must be added to the emulsions [165]. Often the use of cationic emulsifiers suffices, since these generally have an inherent bactericidal or bateriostatic action. Aldehydes, such as formaldehyde or chloral hydrate, or aldehyde precursors are used as added preservatives. Phenol derivatives, such as 2-phenylphenol, 4-chloro-3-cresol or, in cases where it is physiologically safe, pentachlorophenol or its fatty acid esters, are also used. Finally, heterocyclic compounds such as 2-chloroanilinodichlorotriazine or derivatives of 1,2-benzoisothiazolone have been introduced [166]. Table 8 lists common special emulsion promoters.

9. Selection of Emulsifiers [5, p. 200], [6, p. 462], [167]

9.1. Selection Criteria

Emulsion manufacturers are generally confronted with the problem of selecting from hundreds of emulsifiers, only a few of which produce the desired dispersion of the components in each other. Which emulsifier or emulsifier mixture has an optimum effect in a given system depends, on the one hand, on the physical properties of the system and, on the other hand, on the function to be performed in the application. Thus, general practice includes trying out various emulsifiers. The following considerations may make selection simpler, but they also indicate how limited general rules are.

Chemical Structure. The chemical structure of the emulsifier should match the chemical structure of the internal phase. For example, fats can be emulsified with fatty acid esters or sulfated fats. As a rule, aromatic compounds are easier to emulsify with emulsifiers whose hydrophobic section contains aromatic rings. However, mineral oils are more readily emulsified with alkylphenol polyglycol ethers with a shorter polyether chain than with corre-

sponding alcohol polyglycol ethers. The choice of an emulsifier that has proved successful in emulsifying substances with a similar chemical structure is often advisable.

Solubility. The emulsifier should be sparingly soluble in the internal phase and as soluble as possible in the external phase, a requirement that in practice often results in compromises. As a rule, oil-soluble emulsifiers, such as lithium, calcium, magnesium, or aluminum salts of fairly long-chain alkyl carboxylic or sulfonic acids, primarily form w/o emulsions, whereas water-soluble emulsifiers such as the alkali-metal or ammonium salts of the previously mentioned acids are more prone to form o/w emulsions (Bancroft rule [168]).

Volume Ratio. The phase volume ratio (Section 2.7) usually determines the type of emulsion. In general, an excess of oil produces w/o emulsions, which necessitate oil-soluble emulsifiers. Similarly, with an excess of water, o/w emulsions are usually formed, for which water-soluble emulsifiers are used. However, in the manufacture of creams or in the production of water-in-hydrocarbon emulsions for textile printing [163], w/o emulsions with an excess of water are produced. Special oil-soluble emulsifiers such as "Span" types (N106, Table 1) are used [169].

Ionic or Nonionic Emulsifier. Whether an ionic or nonionic emulsifier is used for emulsifying depends on the system. As a rule, nonionic emulsifiers are used to prepare w/o emulsions. The addition of ionic emulsifiers has not proved effective. Nonionic emulsifiers are also often used to prepare o/w emulsions.

Usually, fairly large quantities of the uncharged emulsifier are needed to prepare stable emulsions (Fig. 11 A). In addition, the use of two nonionic components with polyglycol ether chains of different length generally decreases the required emulsifier concentration [170]. The addition of anionic emulsifiers has resulted in mixed emulsifiers, which have found widespread use (Section 3.6).

Several Ionic Emulsifiers. Ionic emulsifiers are usually not used alone (see Section 3.6), but they are used to produce emulsions for achieving special effects. The low stability of these emulsions is then often desirable. Thus, cationic emulsifiers produce a charge reversal in the gravel when they are used in tar emulsions in road paving. The subsequent spontaneous breaking of the emulsion is desirable so that water can rapidly evaporate from the road surface.

Mixed Emulsifiers. As a rule, the use of mixed emulsifiers requires a smaller amount of emulsifier than if nonionic emulsifiers are used alone (Section 3.6). If these emulsifiers are employed, the mixing ratio may determine the type of emulsion, especially if emulsifiers with opposite solubilities are added.

Acidic or Basic Emulsions. In acidic or basic environments, emulsifiers that are sensitive to hydrolysis cannot be used. In salt-sensitive emulsions, nonionic emulsifiers are more suitable than ionic ones, since no possibility of salt exchange exists. When emulsions are exposed to higher temperature, the cloud point of nonionic polyglycol ethers should be considered [70], [171], [172].

9.2. Selection Systems

HLB System. To make the selection of emulsifiers easier, GRIFFIN assigned a dimensionless number between 0 and 20 to each emulsifier to give information on water and oil solubility. Numbers between 0 and 9 characterize oil-soluble hydrophobic products, whereas numbers between 11 and 20 are used for water-soluble oleophobic compounds. The hydrophilic – hydrophobic equilibrium (termed "HLB," which stands for hydrophilic – lipophilic balance) is situated at the center (10) of this scale [169], [173], [174]. Substances with an HLB value of 10 are distributed between the two phases so that the hydrophilic group (molecular mass M_{H}) projects completely into the water while the hydrophobic hydrocarbon group (molecular mass M_{P}) is adsorbed in the nonaqueous phase.

In the ideal case, the HLB of an emulsifier with a molecular mass of M and a hydrophilic portion M_{H} is given by

$$\mathrm{HLB} = 20\frac{M_{\mathrm{H}}}{M} \tag{6}$$

Therefore, the HLB value indicates what mass fraction of the emulsifier projects into the aqueous phase in the ideal case. An advantage of the HLB system is that the HLB value of an emulsifier mixture (HLB_{mi}) is a linear combination of the contributions made by the individual components:

$$HLB_{mi} = g_1 \cdot HLB_1 + g_2 \cdot HLB_2 + \ldots \quad (7)$$

where g_1, $g_2, \ldots$ are the mass fractions of the individual components. If Equation (6) is multiplied by 5, the *Budewitz hydrophilic number,* HN, [175] is obtained:

$$HN = 5HLB \quad (8)$$

For fatty acid esters, the HLB value can be determined from the saponification index I_S of the ester and the acid index I_A of the fatty acid [176]:

$$HLB = 20\left(1 - \frac{I_S}{I_A}\right) \quad (9)$$

For *ethoxylated fatty* acid esters of polyhydric alcohols, (e.g., glycerol or sorbitol) the following simple formula can be used if the mass fractions of alcohol (w_A) and poly(ethylene oxide) (w_E) are known or can be determined [122].

$$HLB = \frac{w_A + w_E}{5} \quad (10)$$

If the hydrophilic portion of the emulsifier consists only of ethylene oxide (w_E), which is known or can be determined, the HLB values are given by Equation (11) [173]:

$$HLB = \frac{w_E}{5} \quad (11)$$

For polyglycol ethers Moore and Bell [177] give the following equation for determining the hydrophilic – lipophilic equilibrium *H/L*:

$$\frac{H}{L} = \frac{\text{number of ethylene oxide groups} \times 100}{\text{number of carbon atoms in the lipophilic part}} \quad (12)$$

For these emulsifiers, Equations (6) – (12) give similar HLB values. Table 9 lists HLB values of nonionic emulsifiers.

Table 9. HLB ranges of some nonionic emulsifiers , p. 202[5].

Emulsifier	HLB range
Fatty acid esters of [169]:	
Ethylene glycol	1.5 – 2.9
Poly(ethylene glycol)	1.8 – 18
Glycerol and polyglycerol	0.8 – 4.5
Sorbitol	1.8 – 8.6
Saccharose	7 – 15
Polyglycol ethers of [169], [174]:	
Alcohols	8.2 – 16.9
Fatty acids	8.1 – 15.0
Glycerides	8.0 – 18.0
Alkylphenols	9.9 – 16.5
Abietic acid	6.7 – 14.7

For *ionic emulsifiers,* no generally applicable method of determining reliable HLB values has been found. When Equation (6) is applied, the HLB values for ionic emulsifiers are too low; i.e., the ionic emulsifier is more hydrophilic than would be expected from the ideal distribution. To take account of this, a correction factor *C* has been included in (Eq. 6) [174]:

$$HLB = 20\frac{M_H}{M} + C \quad (13)$$

Table 10 shows tentative values of *C* for ionic and nonionic emulsifiers.

Table 10. Value of correction factors *C* for HLB values in Equation (13) [174]

Emulsifier	*C* in Equation (13)
Aliphatic polyglycol ethers	−1.2
Aromatic polyglycol ethers with one alkyl group	−1.9
Aromatic polyglycol ethers with two alkyl groups	−4.4
Ethanolamine salts of *n*-dodecylbenzenesulfonic acid	+2.1
Sodium salts of *n*-alkylsulfonates	+5.5
Sodium salts of *n*-alkylsulfates	+6.0

According to Davies [178], the HLB value of an emulsifier can be derived by combining increments of individual fragments, using the following equation (Table 11):

$$HLB = \sum mH_h + nH_l + 7 \quad (14)$$

Table 11. HLB increments according to DAVIES [178] and LIN [179]

Molecule fragment	HLB increment	
	H_h	H_l
$-SO_4Na$	38.7	
$-SO_3Na$	37.4	
$-COOK$	21.1	
$-COONa$	19.1	
$\equiv N$ (tertiary amine)	9.4	
Ester (sorbitan ring)	0.8	
Ester (free)	2.4	
$-COOH$	2.1	
$-OH$ (free)	1.9	
$-O-$	1.3	
$-OH$ (sorbitan ring)	0.5	
$-(CH_2CH_2O)-$	0.33	
$-(CH_2CH_2CH_2O)-$		-0.15
$-CH-$		-0.475
$-CH_2-$		-0.475
$-CH_3-$		-0.475
$=CH-$		-0.475
Benzene ring		-1.662
$-CF_2-$		-0.870
$-CH_3-$		-0.870

where m is the number of hydrophilic groups (increment H_h) and n is the number of CH_2 groups (increment H_l) that occur in the hydrophobic hydrocarbon part of the molecule.

For nonionic emulsifiers, the HLB values calculated by the Davies method usually agree with the Griffin HLB values. For ionic emulsifiers, values are obtained that are much in excess of 20 and, therefore, differ markedly from the Griffin HLB values.

P-Value. HANSCH suggests another method for emulsifier selection. The P-value is the distribution coefficient of compound R between octanol (o) and water (w):

$$P = \frac{c_R\,(o)}{c_R\,(w)} \tag{15}$$

Comparative studies have shown that this distribution coefficient P of compound R consists of increments π_x, in accordance with the following equation [180–182]:

$$\log P = \sum_{1}^{n} \pi_x \tag{16}$$

For hydrophobic parts of molecules, the logarithms of the P values are positive, whereas for hydrophilic portions, they are negative.

For $P = 1$, a substance is uniformly distributed between octanol and water. If $P > 1$ the substance is predominantly soluble in octanol, while if $P < 1$, the compound preferably dissolves in water.

Values of π_x are listed in Table 12 [182]; such values are unknown for ethylene oxide and propylene oxide, and the determination of values of π_x for ionic groups such as the $-SO_3Na$ group is impossible [182, p. 21].

Phase Inversion Temperature (PIT) . SHINODA uses the phase inversion temperature (PIT) to characterize an emulsion. The value of the PIT indicates the temperature at which a water-soluble emulsifier hydrate is transformed into an oil-soluble one [69], [75], [172]. When the PIT is lower, the emulsifier used is more hydrophobic, with a low PIT value corresponding to a low HLB value [183]. In the case of polyglycol ethers, the PIT is comparable to the cloud point [71], [184]. The PIT can be determined visually, electrically (see Section 11.5), or by differential thermal analysis [185]. A direct relationship between PIT and HLB values has only been established in homologous polyglycol ether series [183], [186]. No assessment of the HLB values of ionic emulsifiers has been provided by PITs thus far, although phase diagrams of water and oil with a mixed emulsifier containing an ionic component reveal a phase inversion.

Other Systems. Other classifying indices for emulsions include the R factor [187] and the cohesive energy ratio (CER) [188], [189]. Table 13 compares the numerical values of the different selection systems used in various fields of application [177], [182], [190], [191].

9.3. Assignment of HLB Values

According to experience with the HLB system, an HLB value should be assigned not only to the emulsifier, but also to the substances to be emulsified. The HLB values required for frequently emulsified products are listed in Table 14 [192]. The significance of this for the emulsion manufacturer is as follows: if the HLB value of the product to be emulsified is known or can be determined from Table 14, the emulsifiers or emulsifier mixtures selected for preparing an emulsion should have an HLB value which approximately matches that of the product to be emul-

Table 12. π_x values according to HANSCH [180]

Group	π_x	Group	π_x
Aliphatic group		$-CONH_2$	−1.71
$-CH_3$; $-CH_2-$ (chain)	0.50	$-COCH_3$	−0.71
$-CH_2-$ (cyclic)	0.41	$COOCH_3$, $-OCOCH_3$	−0.27
$-CH-$ (chain branching)	−0.20		
$-NH_2$	−1.19		
$-NHCH_3$	−0.67	**Aromatic group**	
$-N(CH_3)_2$	0.32	benzene ring	2.13
		$-CH_2-C_6H_5-$ (benzyl)	2.69
$-CH_2-NH-CH_2-$	−0.17		
$-CH_2-N(CH_3)-CH_2-$	0.18	$-CH_2-$ (on aromatic group)	0.56
		$-NH_2$	−1.23
$-OH$ (primary)	−1.16	$-OH$ (phenol)	−0.67
$-OH$ (secondary)	−1.39	$-OH$ (benzyl)	−1.59
$-OH$ (tertiary)	−1.49	$-OCH_3$	−0.02
$-OCH_3$	−0.47	$-OCCH$	0.28
$-SCH_3$	0.45	$-CH_2COOH$	−0.72

Table 13. Numerical values for different emulsion selection systems used in various fields of application , p. 205[5]

	HLB	R	CER	PIT	log *P*	H/L
Defoaming agents	0 – 3	$\gg 1$	up to 3.90		7.84 (stearyl alcohol)	
Emulsion, w/o	3 – 8	>1	3.90 to 1.25			20
Wetting agents	7 – 9	≈ 1	1.50 to 1.00			
Emulsion, o/w	8 – 18	<1	1.25 to 0.08			40 to 125
Detergents	11 – 15	<1	0.70 to 0.29	25 to 105		
Solution promoters	12 – 18	<1	0.58 to 0.08		0.32 (2-propanol) −0.66 (n-ethanol)	150

Table 14. HLB values of frequently emulsified products [192], [169]

Emulsified product	HLB	Emulsified product	HLB value
o/w emulsions			
essential oils	12 – 18	nonylphenol	14
avocado oil	9	dichlorobenzene	13
cotton seed oil	10	oleic acid	17
beeswax	12	paraffin oil	11
benzene	15	petroleum	14
gasoline	14	Pur-Cellin oil	9.5
butyl stearate	11	castor oil	14
ethyl benzoate	13	silicone oil 300 CP	11 – 12
carnauba wax	12	sunflower oil	8

mineral oil	10 – 12		
w/o emulsions			
cotton seed oil	5	stearic acid	6
beeswax	4	table paraffin	4
lanolin (wool fat)	8	vaseline	5 – 7
paraffin oil	8		

sified. If the required HLB value is unknown, it can often be determined by a series of tests (see Section 11.5).

Various attempts have been made to determine HLB values experimentally [173], [178–182], [193–199]. For nonionic emulsifiers, all of these methods yield usable HLB values that are often only comparable in homologous series.

Classical emulsification experiments using a test series [169], [173] (see Section 11.5) often result in HLB values that can also be used for emulsifier selection. In such a case, the method of calculation provided is a valuable aid for many emulsion producers.

The HLB system and the other selection systems provide no information on the application properties of emulsions such as their long-term stability or their heat resistance. Therefore, any decision on the suitability of an emulsifier must be based on experimental data [100].

9.4. Selection Procedure

If no details of the phases to be emulsified are known, the following selection procedure can be adopted in practice:

1) Determination of the required HLB value of the substance to be emulsified either from a comparison with the substances in Table 14 or by emulsification experiments using a series of test emulsifiers (see Section 11.5)
2) Selection of emulsifiers or emulsifier mixtures having an HLB value that matches the required HLB value; if no HLB values are known, they can be estimated from the chemical structure of the available emulsifiers by using Equations (6) – (14).
3) Qualitative determination of the solubility of the selected emulsifiers in a test tube; low solubility in the internal phase and good solubility in the external phase are prime requirements for rapid adsorption at the interface between the phases to be emulsified.
4) Determination of the interfacial tension between the phases to be emulsified with and without 5 g/L of emulsifier added (Section 11.4); if the result indicates a marked lowering in the interfacial tension, a necessary condition for emulsification is fulfilled.
5) Emulsification experiments in a glass cylinder, as described in Section 11.1, to test the desired rate of emulsion formation and the required stability
6) If stability over a fairly long period is required, long shelf lives can be simulated in short periods by centrifuging.
7) A large-scale practical test under the required conditions

10. Fields of Application

The applications of emulsions in industry and technology are extremely varied [5, p. 389], [6, p. 465], [19], [20], [22], [29], [171]. Not only do they improve, simplify, or cheapen conventional methods, but emulsions often make new technologies possible. The emulsifiers that are used are of particular interest, since considerable effects are usually achieved with small quantities of substances. Often the addition of wetting agents, solubilizers, thickening agents, or preservatives is indispensable. Since the theoretical aids for preparing emulsions are still only at the initial stage, laborious testing of many emulsifiers is usually unavoidable. A collection of emulsion formulations for a wide variety of applications is found in [15, Vol. II].

The most important applications for emulsions and the assiociated emulsifiers and emulsion promoters are listed on the following pages. The emulsifiers specified are given under the corresponding key numbers in Tables 1, 2, 3, 4, 5, 6, 7, 8. Occasionally, commercial products are mentioned whose composition is not precisely known; these are shown in quotation marks. An F behind the emulsifier designation signals preference for emulsifiers that have double bonds in their hydrophobic part. In such cases, derivatives of oleyl alcohol or oleic acid are usually used. Occasionally substances that are to be emulsified are cited in brackets behind the emulsion type.

10.1. Cosmetics [19, p. 646], [22, p. 167], [29, p. 178], [134],[171, p. 608], [201–203]

Cream bases, w/o, HLB 4 – 6: T103, N315, T101 [204], N314, T102, T106, N301, A101 AA, A104, A401, N102, N104, M101, N105, N106, N107 N109, N304.

Fat and oil emulsions, w/o, HLB 5 – 7: N103, N105, N301, N304, N303; o/w, HLB 12 – 15: N308, N310, N404.
Essential oil emulsions, o/w, HLB 16 – 18: N301, N303, N304, N307, N310, A208 + N303, N303 + N310 + N102.
Paraffin oil emulsions, o/w, HLB 10 – 14: N301/F N105 + 304, N106 + N304, N301 + N303.
Stearic acid emulsions, o/w: N301, N303, N102, N105, or N106 with N304 or N307.
Wax emulsions, o/w, HLB 14 – 16: Borax, N106, N301, N310, N304, individual or mixed with each other.
Lanolin emulsions, o/w, HLB 12 – 14 and w/o: N301.
Silicone emulsions, N301, N310, N301 + N307 [205].
Toothpastes, o/w: A303.
Foam baths, o/w, HLB 14 – 18: A307, A101, A201, A208, A301.
Hair Lotion: K100 with N100 or N300 [206], [207].

10.2. Pharmaceutical Preparations [19, p. 638], [29, p. 178], [171, p. 673], [208],[209, vol. 7/3], [210]

Drug emulsions, o/w: T110, A301, N105, N106, N109 [210], [211], N301, N303, N304 [212], [213], K103, K104, K107, A106, A402.
Ointment bases, [214], [215], w/o, HLB 3 – 6: T101 and H101 with A301 added [164], N102/F, N105/F, alone or mixed with N304, N301, N303 or N307; mixture of T101, T102 or T103 with N301 and H100. o/w, HLB 8 – 14: N301, N303, N304, A301 alone or mixed with each other.
Suppository compound, w/o: N102, N105, N106 alone or mixed with N304 or N307.
Encapsulation: T106.
Injection preparation [216–218]: N307; especially ethoxylated castor oil.

10.3. Agriculture [19, p. 681], [171, p. 722], [219]

Soil improvement: P103, P302, A201 short-chain.
Fertilizer additive: N301
All purpose cleaners: N102, N105, N106, N301, N303, N307, alone or mixed with each other.
Cleaners for fruit and vegetables: N105, N106, N108, M102.
Cleaners for milk churns: K100 [22, p. 178].

10.4. Crop Protection [19, p. 684], [29, p. 182], [209, vol. 7/4],[219–222]

Naturally occurring insecticides (e.g., pyrethrum), o/w: N304.
Chlorinated hydrocarbons, o/w: 208/S, 208/A, or 208/AA with N311, N307, N105, or N106; N301 with A208, "Toxanon 500"; "Emcol N141 B," "Emcol N146," "Emcol N300 B," or "Emcol N500 B," "Emulsogen IC, IT, and 140."
Carbamates, sparingly soluble: A208/AA with N311 or N307.
Carbamates, readily soluble: A209 with A210 "Emulsogen IT."
Phosphoric acid esters [223–225], o/w, HLB 10 – 14: A208/S with N311, N307, N105, or N106; "Atlox 3403," "3404," or "2309"; "Toxanon 888" or "P900"; "Triton X151"; "Emcol N141 B," "Emcol N 146," "Emcol N 300 B;" "Emulsogen ITN."
Fungicides, o/w: A209 or A210 with N311; A208/AA with N311 or N310.
Herbicides, o/w: A208/S with N311 or N307; N304, N307, or N311 with A209, "Emcol N710," "Emcol N311" with A209 or "Tocanon HC-23," "Emulsogen 140 and IT."

10.5. Food Industry [2, p. 29], [19, p. 689], [22, p. 178], [29, p. 177],[34], [35], [171, p. 713], [219], [226]

Table 15 gives a survey of the methods of preparation and the stabilization mechanisms in emulsions used in the foods industry [2, p. 29].
Bread and cakes [207], [227–229], w/o, HLB 4 – 8: T102; T106, N108, N105, N106, N304, or T105, alone or mixed with each other.

Margarine, w/o: T102, T106, N105, N109, A402, A204.
Chocolate [220]: T102.
Fat bloom prevention, w/o, HLB 5 – 10: N105 or N106, alone or with N304.
Sugar frosting, o/w, HLB 14 – 16: N304.
Softeners for caramels and chewing gum, w/o, HLB. 2 – 4: N105.
Prevention of sticking, w/o, HLB 2 – 4: N105.
Ice cream additives [206], [231], w/o, HLB 4 – 6: N105, alone or mixed with N304 or T105.
Wetting of milk and baking powders [232], w/o, HLB 9 – 11: N304.
Custard powder, w/o, HLB 2 – 4: N105.
Drinks industry: T107; T106.
Fruit and vegetables: N 105.
Flavorings, w/o and o/w, HLB 10 – 12: N105 or 106, alone or mixed with N304.
Meat, salad, or other flavoring sauces, o/w:T105 [284].
Food dyes, w/o, HLB 2 – 4: N 105; o/w, HLB 8 – 18: N304.
Foam inhibitors: N109; N406 [201].

10.6. Textile Industry [19, p. 623], [20, p. 2557], [22, p. 160], [29, p. 189], [171, p. 567], [209, vol. 6/5], [233], [234]

Pretreatment agents for wool or jute [235], o/w (oleic acid – mineral oil): N106, N101, A201.
Pretreatment of cotton: o/w: A205, A401, A201, A208, or A201, A208 with N301 or N310.
Spinning preparations and textile lubricants [221], [222], [226] [236–240], o/w (mineral oil), HLB 8 – 12: N165, N106, N304, N307, A402, generally in mixtures, also A208 with N304.
Carrier concentrates [241–243], o/w: A208/S or A208/AA with N301 or N311; N310 with A307.
Level-dyeing assistants with dye affinity [216]: N301, N303, N201, N305.
Level-dyeing assistant with fiber affinity [217], [218]: A303, A301, A208, A213, A210.
Dye liquid formulations, o/w: N301, N310, A201, A301. Solvents: ethylene glycol, propylene glycol, acetic acid, and urea as solubilizer.
Avivages [244–246], o/w (paraffins, waxes, silicones, polyethylene): N100, N202, K110, N204, often mixed with N301, also A307, A402, M102, T101.
Sewing thread, o/w (paraffin): K101, K164, K108 [247].
Waterproofing agents, o/w, HLB 8 – 11 [248–250] (paraffin, waxes): N105, N106, N301, often with R102 or R104 added, and also A208 with N304 or N204 with A101/A.
Waterproofing agents, o/w (polyethylene), HLB 10 – 12: N301, alone or mixed with N106.
Waterproofing agents, o/w (silicones): K 104 and also N301 or N310 with longer ethylene oxide chain.
Fixing accelerators: H108 and also ethoxylated form N301, N310, N303, [18, p. 191], [252], [253].
Printing pastes: H100, A200: o/w or w/o (T109 – T106 – 111 – synthetic latices): N301, branched; N311, A200, A300 [163], [251].
Pad aids, w/o: T109, T111, T108, A201, generally in mixtures; o/w: A301 or N310, alone or in mixtures.
Antistatics: A303, A301, A201, N301, N310, N303, N202, N306, N305, A401, N317.
Flocculating and accelerating agents, o/w: P100, especially P102, P107, P303.

10.7. Plastics Industry [16, vol. 14/1], [19, p. 744], [20, p. 2886],[209, vols. 6/3, 6/4], [254–261]

Emulsion polymerization (EP) [115, vol. 1, p. 64] of butadiene, o/w: A101, A208, A209, A307, A201.
EP of chloroprene, o/w: A108; N310.
EP of styrene, o/w: A208, A301, A303, A307, N301, N303, N310.
EP of vinyl polymers, o/w: A101/short-chain, A404, A201, A206/short-chain.
EP of acrylonitrile – butadiene – styrene (ABS), o/w: A108, A101/S, A208 [262], [263].
EP of polyamide and polyester, o/w: A210 with N301 or N311.
EP of polyethylene, o/w: A301, N204, A207 [264], [265].
EP of acrylonitrile, o/w: A101, P110.

Table 15. Examples of typical food emulsions

Food type	Emulsion	Preparation method	Stabilisation mechanism
Milk	o/w	natural product	natural protein – lipid membrane
Cream	o/w	centrifugation	natural protein – lipid membrane
Ice cream	o/w	homogenization	reconstituted protein membrane
Butter and margarines	w/o	churn/votator	fat crystal network
Sauces	o/w	high-speed mixers/homogenizers	protein – polysaccharide membrane
Fabricated meat products	o/w	low-speed mixers, choppers	gelled protein matrix
Bakery products	o/w	mixers (various)	starch – protein network

EP of acrylonitrile, w/o: A101, N106, K107 [266].
EP of phenol formaldehyde resins, o/w, w/o: T106, A101/S.
EP of acrylamide, w/o: N106.
Bead polymerization, o/w: P102, T105.
Foam plastics, o/w: A202, N109; w/o: N318.
Release agents (silicone emulsions), w/o, HLB 8 – 12: A202, N301, N310, [267].
Microcapsules [268–274], o/w: T106, T102, T105, T107.
Adhesion improvement between fillers and plastics: potassium oleate, N311, A209 [275].
Emulsifiers for nonaqueous systems, o/o: P301, P201, P202, P104, alone or as copolymers with styrene [114].

10.8. Building Industry [13], [19, p. 673], [22, p. 180], [29, p. 186]

Asphalt emulsions [152], [276], [277], w/o, o/w: K110, K101 [278], K108 [279].
Cement thinners [262], [280], [281], w/o: A307, A208, T104 or A110, alone or mixed with N310 or A209, and also silicone emulsions; addition of H500.
Waterproofing of masonry, o/w: A101/barium salt.
Adherents for concrete, o/w (paraffin/mineral oils): N105, N106, N301, often with R102 or R104 added; also A208 with N204 or N204 with A101/A.
Plasters and paints (polymer dispersions) [115, vol. II, p. 32], o/w: N100, N301, N308, N309; mixed emulsifiers P102, P107, H100, H200, H400.
Filler putties (polymer dispersions) [115, vol. II, p. 80], o/w: A201, A208, A301, A401.
Wood impregnation, w/o, o/w: A208 or T104, alone or mixed with N301 or o/w: N310.

10.9. Paints and Coatings [19, p. 721], [20, p. 2880], [29, p. 192],[171, p. 746], [209, vol. 6/6], [211], [256],[282], [283]

Emulsion paints, nonaqueous systems: A108, A109/S, A303, N203 [114].
Emulsion paints, aqueous systems, o/w: N301, N310, N311, A108, A101, N100, T104, T106, A107, A210, A208, P103, A405, T105, N308.
Strippers (paint removers), w/o: N310 alone or mixed with A101 or A201.

10.10. Paper Industry [19, p. 697], [20, p. 2890], [22, p. 177],[29, p. 193], [171], [228–234], [247],[284–290]

Antiresin agents: A209, A201, N100, N300.
Antifroth agents: A101 and many others.
Dispersions of white pigments: A405, A406, P103.
Dispersions of colored pigments: A209, A201.
Coating binders: A201 and many others.
Surface finishing, o/w, conductive papers: K100; absorbent papers: A200; glossy papers: A303; waterproof papers [poly(vinyl chloride) – polyurethanes – silicone – oil]: A201; cardboard articles (paraffin): A201.
Improvement of wet-fastness: P204 [291].
Glueing, o/w: (natural resins – stearyldiketene – T103 – T107 – T106 – P302): A108, A303, alone or mixed with N300.
Sieve and felt cleaning: A201 and many others.
Fiber recovery (emulsion breaking): electrical with addition of A303, N205, P106 [289], [292–294].
Wastepaper recycling [292], [295], [296]: A209, A210.

10.11. Leather Industry [19, p. 693], [20, p. 2898], [171, p. 273],[297–305]

Degreasing, o/w (fats), HLB 2 – 6: N105 mixed with N 304, with solvents added.
Tanning, o/w: N310.
Binder: P103, P304 [298, pp. 750 – 753].
Retanning, o/w: N310.
Dyeing, o/w: P202, N310, N301, N305, N306, [306], [307].
Oiling, o/w, (sperm oil – neat's foot oil – lanolin – chloroparaffin): N105; N301; M100 [308–310].
Finishing [276], [277], o/w (collodium – T106 – T103 –P103 – P107): A303, A210, A301 alone or mixed with N300, N100.
Polishes, w/o: K197/F, alone or mixed with N100, N300.

10.12. Mining [22, pp. 174, 180], [209, vol. 5/4], [311]

For hydraulic fluids, see Section 10.13; for wood treatment, see Section 10.8
Flotation [20, p. 2956], [29, p. 193], [171, p. 836], [209, vol. 4/2], [312], [313].
Flotation of nonferrous metal ores: A407, xanthates.
Flotation of oxidic ores: A101, A201, A301.
Flotation of potassium salts: K103, K104, K107, N202.

10.13. Metal Industry [19, p. 658], [29, p. 2883], [22. pp. 172, 175],[29, p. 221], [171, p. 728]

Cutting, grinding, and drilling oils (cooling lubricants), o/w, HLB 2 – 6: A101/S, A108/S, A109/S, A201/S, N106, N203, N301, N303, N304, N310, N400, H100, K103, K108, H400, and also ionic/nonionic mixtures.
Rolling and drawing oils, o/w, HLB 2 – 6: N106, N203, N301, N303, N310, N400.
Hardening oils, o/w: N301, N310 [247].
Hydraulic oils: N301, N310, with fairly long polyether chain.
Anticorrosion agents, o/w, HLB 2 – 8: A104, A105, A203, A201, A400, K105, T101, [171, p. 858].
Polishing pastes, o/w (mineral oils): N301, N303, N310.
Release agents, o/w (mineral oils): N300, A203.
Metal cleansers [171, p. 550], aqueous, o/w (soda – sodium hydroxide solution – sodium metasilicate – sodium tripolyphosphate): N310, N305, N316, K102.
Metal cleansers, nonaqueous, w/o: A306.
Metal dryers: K100, M100.

10.14. Electroplating [19, p. 664], [22, p. 173], [29, p. 193], [314], [315]

Electrolytic baths: A207 [316], (Bayer FT 248) [317], A301, A201, A102, A208 [318], P109, N308, N301, N305, N316.
Polishing of steel, tantalum, or nickel: N-acylsulfonylureas A201, A301, P106, T105.

10.15. Polishes, Manufacture and Removal [171, p. 821], [247], [317], [319–321]

Wax emulsions, o/w: A102, A207, N301, N304, morpholine soaps: addition of A207, Bayer FT 248.
Polyethylene emulsions, o/w: A301, A207, K101, N105, N106, N301 or, N304 alone or mixed with A210, P103 or P104, P202 [322].
Silicone emulsions, o/w: A301, morpholine oleate, A103/A, oleic acid esters, A402, addition of A207 (Bayer FT 248).
Car washes: wax or silicone emulsions with K103 added.
Wax film removal (gasoline – water emulsion): N100, N300.

10.16. Petroleum Industry [323]

Drilling aids, o/w: A101, T104, T105, A208, K103, K108, K109.
Deemulsifiers [16, vol. I/1, p. 213], [324], w/o: A201/F, A301/F, A210, A201/A, A208/A, M100, K108, N300, generally mixed.
Additives to flood water, o/w: N201, K103, K104, N305, N306, N303, N310.

For major spills on transportation, [325], [326], o/w: N300/short polyether chain length "Dispersole."

10.17. Mineral Oil Industry [19, p.667], [29, p. 221], [171, p. 793], [323],[388]

Fuel additives, w/o, HLB 2 – 6: A402/A, N105, N202, succinimides, succinamides, K108, polyisobutaneamines, and other [29, p. 227], [327].
Heating oil additives: P303, ammonium salts of medialanic acid.
Lubricant additives, w/o, HLB 2 – 6: A101/S, A108/S, A109/S, A201/S, A207/S, A404, P105: polyisobutylsuccinimide, P100, and others [29, pp. 248 – 250], [215], [328], [329].
Lubrifying additives, w/o (gasoline, diesel fuel) [5, p. 418]: N310 with various chain lengths, mixtures of N106 with N304 [330], or mixtures of N203, N105 with N306 [331], [332].

10.18. Adhesives Industry [22, p. 177], [29, p. 193]

Rubber adhesives: N100, N300.
Vinyl resin adhesives: A301, A307, N308 [333].
Adhesive dispersions: [115, Vol. II, p. 82].
Furniture glue, o/w: P102, P106.
Packaging industry, o/w: P102, P303, P103, P301, P304, P302, polychloroprene, P107.
Building industry, o/w: P102, P103, P301 for tiles, polychloroprene.
Leather industry, o/w: P107, P304, polychloroprene.
Textile industry (lamination coating): P102, P303, P107.

10.19. Photographic Industry [171], [334–338]

Wetting agents in pouring solutions [339], o/w, HLB 8 [340]: T110, A206, A201, A208, A304, A209, N310, N109, N106, N310, N305, A207 (Bayer FT 248).
Antistatics [341]: A301, A206, M102, K110, mixtures of M102 or K110 with A102, A207, or K111.
Lubricants, o/w (stearic acid – wax – polyethylene or silicone oil): short-chain N301 with A209 added.
Color component emulsions [342], o/w or w/o: A201, A210, A301, A204 [343], A209, alone or mixed with T110 [344], [345].
Processing baths: N101 with A201 added, A301, Agepon (A301 + A205 + A206 + N301).

10.20. Chemical Industry [19, p. 744], [20, p. 2886], [254–256]

Reaction accelerators [16, vol. V/3, p. 516], o/w: A201, A208, A209, N301, N310.
Extracting agent additives [346], [347], w/o: A208, N301, N310 [246], [347].
Micellar catalysis [348–352]: A301, P104.

10.21. Detergents and Cleansers

Protective colloids, o/w: T105, A405.
Optical brighteners, o/w: N310.
Cleaning intensifiers [353], w/o: A101/A, A101/AA, A201/A, A201/AA, A208/A, A207/AA, A206/A, A206/AA, N301, N310, H400, alone or mixed.
Industrial and foam cleansers, o/w: A201, A208, N301, N310, alone or mixed.
Washing liquids, o/w: A201, A208, N301, N310, alone or mixed.
Low-phosphate detergents [354]: P302 + A405 + 308.

10.22. Special Applications [5, p. 436]

Fire fighting: A301, A307, N100, M101 with A209 added, H207.
Evaporation retarders: N301 with 1 – 3 ethylene oxide.
Glass fiber reinforcing agents: N103, P101, silicones.
Window cleaning agents: N310.
Antidust agents: A104/F, A301/F, alone or mixed with N301, N310.

11. Investigation of Emulsions [15, vol. I, p. 53]

11.1. Stability [355]

The simplest method of determining stability is to measure *settling or creaming time* in a graded cylinder [356]. Poor emulsions separate rapidly, whereas good ones remain stable for a prolonged period.

The ability to wet the glass wall provides information about the quality of the emulsion. Stable o/w emulsions leave a coherent film on a moist wall, whereas with unstable emulsions, the film breaks up.

When the *spontaneous emulsification* of an emulsion concentrate is tested, droplets are added to the water in a stationary graded cyclinder and should rapidly become finely dispersed without a supply of mechanical energy.

Microscopic investigation easily shows whether the instability of an emulsion is due to reversible sedimentation or to irreversible coalescence. With very small droplets, particularly in colloidal emulsions, electron microscopy is required. When stability is tested, the investigations should be repeated at specified time intervals [357].

Centrifugation is the most rapid method of testing the stability of an emulsion [358]. If it does not break when centrifuged at ca. 300 rpm for 30 min, an emulsion may be assumed to have long-term stability. On the other hand, if it breaks, it may nevertheless be stable on standing undisturbed for a prolonged period.

Increase in *turbidity* [359], [360] is an indication of an increase in droplet size, which can be measured with an nephelometer [361], [362]. In the case of colorless emulsions, particularly colloidal emulsions the light transmission, for example at 700 µm, is a measure of the cloudiness caused by scattering. This can be readily observed and is easy to record.

Simple physical parameters are also suitable for assessing the stability. Useful information on emulsion stability can be derived from regular determination of *density, viscosity,* and particular, of *droplet size* and *droplet size distribution* [357]. The coalescence time is measured directly by determining the time required by the oil droplets to coalesce at the water – oil interface [98].

The only method for determining the *long-term stability* is to store the emulsions as long as possible under the conditions to which they will later be subjected.

In the case of industrial emulsions, the following properties are important: shelf life [339], [363], heat resistance, cold resistance, resistance to change in pH, resistance to the addition of salt, and resistance to mechanical action. The test procedures for these depend on the particular application, and the specified test methods should be modified accordingly. For example, a stability test should be repeated after a specified storage time or heat treatment.

11.2. Emulsion Type

A number of methods have been developed for determining the emulsion type [364, p. 129 – 131], [365]. A very simple and reliable method is the dilution test, since only o/w emulsions can be diluted with water. This test can also be performed on a small scale, the drop dilution method [13]. In this method, a drop of the emulsion on a glass plate is brought in contact with a drop of water. Quick spreading of the emulsified particles indicates an o/w emulsion, whereas the formation of a clear phase boundary characterizes a w/o emulsion. The result can be checked by repeating the experiment with a drop of benzene, in which case the situation should be reversed.

The Roberton dyeing test utilizes the solubility of a dye in the emulsion phase [366]. Coloration is produced in o/w emulsions by water-soluble dyes such as methylene blue or malachite green, but in w/o emulsions by oil- or fat-soluble dyes. The procedure, which involves a mixture of two dyes, is as follows:

A red, fat-soluble and a green, water-soluble dye are separately triturated with talc in a ratio of 1 : 1 and then intimately mixed with each other. This mixture is dusted onto a filter paper in a layer so thin that it can scarcely be seen. The coated paper is colored green by a drop of water and red by a drop of oil. If a drop of an o/w emulsion is applied to the paper, the center is red and the outside rim green. This effect is reversed for a w/o emulsion. To examine pastes, creams, and other emulsions of similar consistency, a thin

coating is smeared onto a microscope slide. After sprinkling an extremely thin layer of the dye mixture onto it, the slide is heated to 50 °C and the colors are observed as described above.

The paper method is based on the different ways in which paper is wetted by o/w or w/o emulsions. The rate of wetting being determined by the external phase. Since water rapidly wets filter paper, but oil only wets it slowly, the external water is seen to spread out rapidly in an o/w emulsion while a drop of a w/o emulsion applied to the filter papter initially remains spherical. Instead of filter paper, an absorbent fabric or a porous earthenware plate may also be used.

The *electrical conductivity* of o/w emulsions is higher than that of w/o emulsions [367]. The method benefits from a low electrolyte content since the phase reversal point can easily be determined. The use of a microwave resonance dielectrometer for determining emulsion type has been described [368].

11.3. Droplet Size and Droplet Size Distribution [27, p. 136]

A microscope often suffices to determine the droplet size and distribution [369]. Agglomeration or coalescence of the emulsion droplets can easily be distinguished. Even a semiquantitative measurement with a microscope stage micrometer provides usable information on droplet distribution.

To eliminate Brownian motion, the emulsion is allowed to dry partially or completely on the slide. To the same purpose, the addition of thickening or gelling agents is often effective [370]. Microprojection [371] or microphotography are also used.

More precise counts may be made with the hemocytometer [91] or the Heller chamber [372]. Automatic counting equipment has been developed for counting good micrographs [373], [374].

With finely dispersed or colloidal emulsions, the resolution of the light microscope is inadequate [101]. This has been overcome by using either the Coulter counter [375–377] or the electron microscope [378].

A freeze-drying method has been developed for electron microscope studies [379], [380]. In this method, the emulsion is frozen very quickly, and the external phase is then allowed to sublime from the solidified emulsion. This method usually works well in the case of o/w emulsions.

Sedimentation methods with or without centrifugal acceleration can also be used to determine the droplet distribution. Large droplets fall or rise more rapidly than small droplets (Stokes's law) [38, p. 136].

The measurement of cloudiness and light transmission has already been referenced in Section 11.1. Computer programs have now been developed that can be used to determine the mean droplet radius from measurements of light transmission. Droplet size distributions have also been calculated for o/w emulsions and are said to agree well with experimental data [380], [381]. Density changes can only be determined for emulsions that are not too stable [373], [382].

11.4. Interfacial Tension [383]

The following methods may be used to measure the interfacial tension between the phases to be emulsified:

1) geometrical measurement of drops, bubbles, and meniscuses [384]
2) maximum bubble pressure method [385]
3) Lenard anchor or ring method [386]
4) plate method [387]
5) capillary wave method [388]
6) spinning drop method [389], [390]

The ring method has been automated [391]. The spinning drop method can only be applied to o/w emulsions. Small interfacial tensions can be measured.

The methods listed above cannot be used to measure the interfacial tension if the interface between the two phases is not sharp. The decrease in interfacial tension on addition of emulsifiers is also measured inaccurately when very low interfacial tensions are involved; this is the case when an efficient emulsifier is added to two phases both having a low surface tension. In such cases, measurements of the surface tension of the phases involved [392] with and without the addition of emulsifier provide a rough guide to the usability of an emulsifier.

11.5. Required HLB Value

To determine the required HLB value of a substance experimentally, two emulsifiers with known HLB values that are as different as possible are mixed in different ratios. This produces a series of mixed emulsifiers with continuously changing HLB values.

An example is the mixture of Span 60 (sorbitan monostearate) having an HLB value of 4.7 with Tween 60 (poly(ethylene oxide) – sorbitan monostearate) having an HLB value of 14.9 (Table 16). Mixtures with different HLB values are obtained [169, p. 7].

Emulsions of the substance to be emulsified are then prepared with these emulsifier mixtures to determine which emulsion is the most stable. The HLB value of the emulsifier mixture used for the most stable emulsion corresponds to the HLB value of the substance to be emulsified. Good quality emulsions of that substance should then be obtained with the aid of emulsifiers having comparable HLB values.

Table 16. Emulsifier mixtures with continuously changing HLB values

Emulsifier mixture		Calculated HLB
Span 60, %	Tween 60, %	value (Eq. 7)
100	0	4.7
87	13	6.0
68	32	8.0
48	52	10.0
28	72	12.0
6	94	14.0
0	100	14.9

The *water number* which is usually proportional to the HLB value for nonionic emulsifiers, can be determined simply and rapidly [197], [198].

In this method, 1 g of the substance whose HLB value is to be determined is dissolved in a mixture consisting of 4 % benzene and 96 % dioxane. The volume of water required to produce the first permanent cloudiness is proportional to the HLB value of the substance.

The *cloud point* [71] can also be determined rapidly and conveniently for polyglycol ether; the cloud point corresponds to the PIT (see Section 9.2), which in turn corresponds to the HLB value of polyglycol ethers.

To carry out the determination, 1 g of the polyglycol ether is heated in 100 mL of distilled water until a cloudy solution is obtained. By slow cooling, the temperature is determined at which the solution becomes clear. Semiautomatic [393] and automatic equipment [394], [395] is now available for determining the cloud point. If the cloud point is above 95 °C, pressurized equipment may be employed [27], [75]. The addition of salts (50 g of NaCl per liter of water) or solvents (such as ethylene glycol monobutyl ether) lower the cloud point, whereas acids, such as acetic acid, increase the cloud point [27], [396]. Figure 14 plots the cloud point of 4-isononylphenol against the HLB value as determined from Equation (13). Poly(glycol ethers) occasionally emulsify the precipitate; in such cases the addition of a trace of salt (e.g., soidum sulfate) is required, or the cloud point must be determined in soft water.

Figure 14. Cloud point vs. HLB value of 4-isononylphenol polyglycol ethers [6, p. 216]
a) 1 % solution in 25 % aqueous solution of ethylene glycol butyl ether; b) 1 % solution in water; c) 1 % solution in 10 % acetic acid (Δ)

11.6. Physical Parameters of Emulsions

Density. The simplest method of determining the density is to use a Mohr's balance. This can provide reasonable values even for viscous emulsions. The density of low-viscosity emul-

sions can also be determined with a pycnometer or a hydrometer.

Viscosity. The viscosity of emulsions is measured for such purposes as quality control [397] or rheological studies. It can be determined with conventional instruments such as the Höppler viscometer [398] or the rotational viscometer [4, p. 217], [398], [399]. Capillary viscometers can also be used [38, p. 483 and 478]. The surface viscosity can be measured with several methods [383]. The generation of low-frequency longitudinal waves on the surface of a film balance [185] produces usable, self-consistent results [402], [403].

Zeta Potential. Various methods are known for determining the zeta potential ξ [192], [404], [405]. A widespread method is to measure the migration velocity θ of an electrically charged droplet in an electric field (E). The emulsion droplets are usually negatively charged and migrate, with their electric double layer and diffuse ion cloud, toward the anode. The zeta potential is calculated from the following equation:

$$\zeta = \frac{4\pi\eta\vartheta}{\varepsilon E} \tag{17}$$

where ε is the dielectric constant and η the viscosity of the external phase.

This method can also be carried out on a microscopic scale [399]. In low-viscosity fine emulsions, the Brownian motion often interferes with the migration, thus making quantitative determination of the zeta potential inaccurate. However, determination of the sign of the charge from the direction of droplet migration is always easy.

Spectrometry. IR and UV spectrometry is used widely [406] for process control and for determining the chemical structure of unknown emulsifiers. Aromatic groups can readily be determined quantitatively by UV spectrometry, whereas ester and amine groups are easily determined quantitatively by IR spectrometry. For comparison, collections of emulsifier spectra are available [407], [408]. An example of a spectrometric determination of an increase in solubility caused by emulsifier addition is shown in Figure 3.

Conductivity. Conductivity measurements can be used to determine the emulsion type (Section 11.2), the PIT (Section 9.2) [409], or for quality control [410].

X-ray Diffraction. Both wide-angle and small-angle measurements are employed to investigate the crystalline [38, p. 227] or liquid – crystalline properties of emulsifiers or emulsifier – solvent mixtures. These methods allow the investigation of the mesomorphic phases that occur between an emulsifier and water or some other solvent [411], [412].

Phase Diagram. The theoretical basis for three-component phase diagrams has been developed predominantly by Kahlweit and coworkers [413], [414].

Abstract

The article contains sections titled:

1. Introduction
1.1. History
1.2. Enzyme Nomenclature
1.2.1. General Principles of Nomenclature
1.2.2. Classification and Numbering of Enzymes
1.3. Structure of Enzymes
1.3.1. Primary Structure
1.3.2. Three-Dimensional Structure
1.3.3. Quaternary Structure, Folding, and Domains
1.3.4. The Ribozyme
1.4. Enzymes and Molecular Biology
1.4.1. Biosynthesis of Enzymes
1.4.2. Enzymes and DNA
2. Catalytic Activity of Enzymes
2.1. Factors Governing Catalytic Activity
2.1.1. Temperature
2.1.2. Value of pH
2.1.3. Activation
2.1.4. Inhibition
2.1.5. Allostery
2.1.6. Biogenic Regulation of Activity
2.2. Enzyme Assays
2.2.1. Reaction Rate as a Measure of Catalytic Activity
2.2.2. Definition of Units
2.2.3. Absorption Photometry
2.2.4. Fluorometry
2.2.5. Luminometry
2.2.6. Radiometry
2.2.7. Potentiometry
2.2.8. Conductometry
2.2.9. Calorimetry
2.2.10. Polarimetry

2.2.11. Manometry
2.2.12. Viscosimetry
2.2.13. Turbidimetry
2.2.14. Immobilized Enzymes
2.2.15. Electrophoresis
2.3. Quality Evaluation of Enzyme Preparations
2.3.1. Quality Criteria
2.3.2. Specific Activity
2.3.3. Protein Determination
2.3.4. Contaminating Activities
2.3.5. Electrophoretic Purity
2.3.6. High-Performance Liquid Chromatography
2.3.7. Performance Test
2.3.8. Amino Acid Analysis and Protein Sequence Analysis
2.3.9. Stability
2.3.10. Formulation of Enzyme Preparations
3. General Production Methods
3.1. Microbial Production
3.1.1. Organism and Enzyme Synthesis
3.1.2. Strain Improvement
3.1.3. Physiological Optimization
3.1.4. The Fermentor and its Limitations
3.1.5. Process Design
3.1.6. Modeling and Optimization
3.1.7. Instrumentation and Control
3.2. Isolation and Purification
3.2.1. Preparation of Biological Starting Materials
3.2.1.1. Cell Disruption by Mechanical Methods
3.2.1.2. Cell Disruption by Nonmechanical Methods
3.2.2. Separation of Solid Matter
3.2.2.1. Filtration
3.2.2.2. Centrifugation
3.2.2.3. Extraction
3.2.2.4. Flocculation and Flotation
3.2.3. Concentration
3.2.3.1. Thermal Methods
3.2.3.2. Precipitation
3.2.3.3. Ultrafiltration
3.2.4. Purification
3.2.4.1. Crystallization
3.2.4.2. Electrophoresis
3.2.4.3. Chromatography
3.2.5. Product Formulation
3.2.6. Waste Disposal
3.3. Immobilization
3.3.1. Definitions
3.3.2. History
3.3.3. Methods
3.3.3.1. Carrier Binding
3.3.3.2. Cross-linking
3.3.3.3. Entrapment
3.3.4. Characterization
3.3.5. Application

4. Discovery and Development of Enzymes
4.1. Enzyme Screening
4.1.1. Overview
4.1.2. Natural Isolate Screening
4.1.3. Molecular Screening
4.1.4. Environmental Gene Screening
4.1.5. Genomic Screening
4.1.6. Proteomic Screening
4.2. Protein Engineering
4.2.1. Introduction
4.2.2. Application of Protein Engineering in Academia and Industry
4.2.3. Outlook
5. Industrial Enzymes
5.1. Enzymes in Food Applications
5.1.1. Enzymes in Baking
5.1.1.1. Introduction
5.1.1.2. Amylases
5.1.1.3. Xylanases
5.1.1.4. Oxidoreductases
5.1.1.5. Lipases
5.1.1.6. Proteases
5.1.1.7. Transglutaminase
5.1.2. Enzymes in Fruit Juice Production and Fruit Processing
5.1.2.1. Introduction
5.1.2.2. Biochemistry of Fruit Cell Walls
5.1.2.3. Cell-Wall-Degrading Enzymes
5.1.2.4. Apple Processing
5.1.2.4.1. Apple Pulp Maceration
5.1.2.4.2. Apple Juice Depectinization
5.1.2.5. Red-Berry Processing
5.1.2.6. Tropical Fruit and Citrus Processing
5.1.2.7. Conclusion
5.1.3. Enzymes in Brewing
5.1.3.1. Introduction
5.1.3.2. Enzymes in Malting and Mashing
5.1.3.3. Enzymes for Problem Prevention or Solving
5.1.3.3.1. Bacterial *α*-Amylase in Mashing
5.1.3.3.2. Fungal *α*-Amylase in Fermentation
5.1.3.3.3. *β*-Glucanase in Mashing
5.1.3.3.4. Cysteine Endopeptidases (Postfermentation)
5.1.3.3.5. Glucoamylase in Mashing
5.1.3.4. Enzymes for Process Improvement
5.1.3.4.1. Adjunct Brewing
5.1.3.4.2. Improved Mashing Processes
5.1.3.4.3. Shelf-Life Improvement
5.1.3.4.4. Accelerated Maturation
5.1.3.4.5. Starch-Haze Removal
5.1.3.5. Special Brewing Processes
5.1.4. Enzymes in Dairy Applications
5.1.4.1. Introduction
5.1.4.2. Cheesemaking
5.1.4.2.1. Cheesemaking Process
5.1.4.2.2. Mechanism of Renneting

5.1.4.2.3. Types of Coagulants
5.1.4.2.4. Properties of Coagulating Enzymes
5.1.4.2.5. Cheese Ripening
5.1.4.2.6. Cheese Flavors and Ripening Acceleration
5.1.4.2.7. Lipase
5.1.4.2.8. Lysozyme
5.1.4.2.9. Milk Protein Hydrolysates
5.1.4.2.10. Transglutaminase
5.1.4.3. Milk Processing
5.1.4.3.1. *β*-Galactosidase
5.1.4.3.2. Other Enzymes
5.1.5. Other Food Applications
5.1.5.1. Introduction
5.1.5.2. Meat and Fish
5.1.5.2.1. Meat Processing
5.1.5.2.2. Fish Processing
5.1.5.3. Protein Cross-linking
5.1.5.4. Flavor Development
5.1.5.4.1. Protein Hydrolysis
5.1.5.4.2. Lipid Hydrolysis
5.1.5.5. Egg powder
5.1.5.6. Oils and Fats
5.1.5.6.1. Fat Splitting
5.1.5.6.2. Interesterification
5.1.5.6.3. Esterification
5.1.5.6.4. Oil Degumming
5.2. Enzymes in Nonfood Applications
5.2.1. Enzymes in Household Detergents
5.2.1.1. Historical Development
5.2.1.2. Laundry Soils
5.2.1.3. Detergent Composition and Washing Process
5.2.1.3.1. Washing Process
5.2.1.3.2. Detergent Compositions
5.2.1.4. Enzyme-Aided Detergency and Soil Removal
5.2.1.5. Detergent Enzyme Performance Evaluation and Screening
5.2.1.6. Enzyme Types
5.2.1.6.1. Proteases
5.2.1.6.2. Amylases
5.2.1.6.3. Lipases
5.2.1.6.4. Cellulases
5.2.1.6.5. Mannanase
5.2.1.7. Future Trends
5.2.2. Enzymes in Automatic Dishwashing
5.2.2.1. Introduction
5.2.2.2. Characteristics of Enzymes for ADDs
5.2.2.3. Proteases
5.2.2.3.1. Proteins: The Substrate of Proteases
5.2.2.3.2. Proteases for ADDs
5.2.2.4. Amylases
5.2.2.4.1. Starch: The Substrate of Amylases
5.2.2.4.2. Amylases for ADDs
5.2.2.5. Other Enzymes
5.2.2.6. Automatic Dishwashing Detergents

5.2.2.6.1. Composition of Automatic Dishwashing Detergents
5.2.2.6.2. Application of Enzymes in ADD
5.2.2.6.3. Stability and Compatibility
5.2.3. Enzymes in Grain Wet-Milling
5.2.3.1. Introduction
5.2.3.2. Overview of the Conversion of Corn to HFCS
5.2.3.2.1. Corn Steeping
5.2.3.2.2. Coarse Grinding and Germ Removal by Cyclone Separation
5.2.3.2.3. Fine Grinding and Fiber Removal by Screening
5.2.3.2.4. Centrifugation and Washing to Separate Starch from Protein
5.2.3.2.5. Hydrolysis with *α*-Amylase (Liquefaction)
5.2.3.2.6. Hydrolysis with Glucoamylase (Saccharification)
5.2.3.2.7. Isomerization with Glucose Isomerase
5.2.3.2.8. Fructose Enrichment and Blending
5.2.3.3. *α*-Amylase
5.2.3.3.1. Origin and Enzymatic Properties
5.2.3.3.2. Structure
5.2.3.3.3. Industrial Use
5.2.3.4. Glucoamylase
5.2.3.4.1. Origin and Enzymatic Properties
5.2.3.4.2. Structure
5.2.3.4.3. Industrial Use
5.2.3.5. Pullulanase
5.2.3.5.1. Origin and Enzymatic Properties
5.2.3.5.2. Structure
5.2.3.5.3. Industrial Use
5.2.3.6. Glucose Isomerase
5.2.3.6.1. Origin and Enzymatic Properties
5.2.3.6.2. Structure
5.2.3.6.3. Industrial Use of Glucose Isomerase
5.2.3.7. Use of Wheat Starch
5.2.4. Enzymes in Animal Feeds
5.2.4.1. Introduction
5.2.4.2. Enzymes Used in Animal Feed
5.2.4.2.1. Fiber-Degrading Enzymes
5.2.4.2.2. Phytic Acid Degrading Enzymes (Phytases)
5.2.4.2.3. Protein-Degrading Enzymes (Proteases)
5.2.4.2.4. Starch-Degrading Enzymes (Amylases)
5.2.4.3. Future Developments
5.2.5. Enzymes in Textile Production
5.2.5.1. Introduction
5.2.5.2. Cellulose Fibers
5.2.5.2.1. Desizing of Cotton Cellulose Fibers
5.2.5.2.2. Scouring of Cotton
5.2.5.2.3. Bleaching of Cotton
5.2.5.2.4. Removal of Hydrogen Peroxide
5.2.5.2.5. Cotton Finishing
5.2.5.2.6. Ageing of Denim
5.2.5.2.7. Processing of Man-Made Cellulose Fibers
5.2.5.2.8. Processing of Bast Fibers
5.2.5.3. Proteinous Fibers
5.2.5.3.1. Wool Processing
5.2.5.3.2. Degumming of Silk

5.2.5.4. Textile Effluent Treatment and Recycling
5.2.5.5. Outlook
5.2.6. Enzymes in Pulp and Paper Processing
5.2.6.1. Introduction
5.2.6.2. Enzymes
5.2.6.2.1. Cellulases
5.2.6.2.2. Hemicellulases
5.2.6.2.3. Lignin-Modifying, Oxidative Enzymes
5.2.6.3. Enzymes in Pulp and Paper Processing
5.2.6.3.1. Mechanical Pulping
5.2.6.3.2. Chemical Pulping
5.2.6.3.3. Bleaching
5.2.6.3.4. Papermaking
5.2.6.3.5. Deinking
5.3. Development of New Industrial Enzyme Applications
5.3.1. Introduction
5.3.2. Enzymes in Cosmetics
5.3.2.1. Hair Dyeing
5.3.2.1.1. Oxidases
5.3.2.1.2. Peroxidases
5.3.2.1.3. Polyphenol Oxidases
5.3.2.2. Hair Waving
5.3.2.3. Skin Care
5.3.2.4. Toothpastes and Mouthwashes
5.3.2.5. Enzymes in Cleaning of Artificial Dentures
5.3.3. Enzymes for Preservation
5.3.4. Enzymes in Hard-Surface Cleaning
5.3.4.1. Enzymes in Membrane Cleaning
5.3.4.1.1. Proteases
5.3.4.1.2. Hemicellulases
5.3.5. Enzymes Generating a pH Shift
5.3.6. Enzymes in Cork Treatment
5.3.7. Enzymes in Oil-Field Applications
5.3.8. Enzymes in Wastewater Treatment
5.3.9. Enzymes for Polymerisation: Wood Fiberboard Production
5.4. Overview of Industrial Enzyme Applications
6. Nonindustrial Enzyme Usage
6.1. Enzymes in Organic Synthesis
6.1.1. Introduction
6.1.2. Examples of Enzymatic Conversions
6.1.2.1. Syntheses by Means of Hydrolases
6.1.2.2. Reduction of CO and CC Bonds
6.1.2.3. Oxidation of Alcohols and Oxygenation of CH and CC Bonds
6.1.2.4. CC Coupling
6.1.2.5. Formation of Glycosidic Bonds
6.1.2.6. Enzymatic Protecting Proup Techniques
6.1.3. Enzyme-Analogous Catalysts
6.1.4. Commercial Applications
6.1.4.1. General
6.1.4.2. Nonstereoselective Biocatalytic Reactions
6.1.4.3. Biocatalytic Resolution Processes
6.1.4.3.1. Enzymatic Acylation of Amino Groups
6.1.4.3.2. Enzymatic Hydrolysis of Hydantoins

6.1.4.3.3. Enzymatic Hydrolysis of Lactams
6.1.4.3.4. Enzymatic Hydrolysis of CO Bonds
6.1.4.3.5. Enzymatic Hydrolysis of Nitriles
6.1.4.3.6. Enzymatic Cleavage of *threo* Aldol Products
6.1.4.4. Biocatalytic Asymmetric Synthesis
6.1.4.4.1. Biocatalytic Reductive Amination of CO Bonds
6.1.4.4.2. Biocatalytic Hydrocyanation of CO Bonds
6.1.4.4.3. Biocatalytic Addition of Water to CO Bonds
6.1.4.4.4. Biocatalytic Amination of CC Bonds
6.1.5. Outlook
6.2. Therapeutic Enzymes
6.2.1. Requirements for the Use of Enzymes in Therapy
6.2.2. Coping with Peculiar Protein Properties
6.2.3. Sources of Enzymes and Production Systems
6.2.4. Overview of Therapeutic Enzymes
6.2.4.1. Oxidoreductases
6.2.4.2. Transferases
6.2.4.3. Esterases
6.2.4.4. Nucleases
6.2.4.5. Glycosidases
6.2.4.6. Proteases

6.4.4. Other Food Ingredients
6.5. Enzymes in Genetic Engineering
6.5.1. Restriction Endonucleases and Methylases
6.5.1.1. Classification
6.5.1.2. Activity of Class II Restriction Endonucleases
6.5.1.2.1. Reaction Parameters
6.5.1.2.2. Additional Structural Requirements Influencing Activity
6.5.1.3. Specificity of Class II Restriction Endonucleases
6.5.1.3.1. Palindromic Recognition Sequences
6.5.1.3.2. Nonpalindromic Recognition Sequences
6.5.1.3.3. Isoschizomers
6.5.1.4. Changes in Sequence Specificity
6.5.1.5. Novel Class II Restriction Endonucleases
6.5.2. DNA Polymerases
6.5.2.1. *Escherichia coli* DNA Polymerase I
6.5.2.2. Klenow Enzyme

6.5.2.3. T4 DNA Polymerase
6.5.2.4. Reverse Transcriptase
6.5.2.5. Terminal Transferase
6.5.3. RNA Polymerases
6.5.3.1. SP6 RNA Polymerase
6.5.3.2. T7 RNA Polymerase
6.5.4. DNA Nucleases
6.5.4.1. DNase I
6.5.4.2. Exonuclease III
6.5.4.3. Nuclease S1
6.5.4.4. Nuclease Bal 31
6.5.5. RNA Nucleases
6.5.5.1. RNase H
6.5.5.2. Site-Specific RNases
6.5.5.2.1. RNase A
6.5.5.2.2. RNase CL3
6.5.5.2.3. RNase T_1
6.5.5.2.4. RNase U_2
6.5.5.2.5. Nuclease S7
6.5.5.2.6. Site-Specific RNases in RNA Sequence Analysis

1. Introduction

Enzymes are the catalysts of biological processes. Like any other catalyst, an enzyme brings the reaction catalyzed to its equilibrium position more quickly than would occur otherwise; an enzyme cannot bring about a reaction with an unfavorable change in free energy unless that reaction can be coupled to one whose free energy change is more favorable. This situation is not uncommon in biological systems, but the true role of the enzymes involved should not be mistaken.

The activities of enzymes have been recognized for thousands of years; the fermentation of sugar to alcohol by yeast is among the earliest examples of a biotechnological process. However, only recently have the properties of enzymes been understood properly. Indeed, research on enzymes has now entered a new phase with the fusion of ideas from protein chemistry, molecular biophysics, and molecular biology. Full accounts of the chemistry of enzymes, their structure, kinetics, and technological potential can be found in many books and series devoted to these topics [1-5]. This chapter reviews some aspects of the history of enzymes, their nomenclature, their structure, and their relationship to recent developments in molecular biology.

1.1. History

Detailed histories of the study of enzymes can be found in the literature [6], [7].

Early Concepts of Enzymes. The term “enzyme” (literally “in yeast”) was coined by KÜHNE in 1876. Yeast, because of the acknowledged importance of fermentation, was a popular subject of research. A major controversy at that time, associated most memorably with LIEBIG and PASTEUR, was whether or not the process of fermentation was separable from the living cell. No belief in the necessity of vital forces, however, survived the demonstration by BUCHNER (1897) that alcoholic fermentation could by carried out by a cell-free yeast extract. The existence of extracellular enzymes had, for reasons of experimental accessibility, already been recognized. For example, as early as 1783, SPALLANZANI had demonstrated that gastric juice could digest meat in vitro, and SCHWANN (1836) called the active substance pepsin. KÜHNE himself appears to have given trypsin its present name, although its existence in the intestine had been suspected since the early 1800s.

Enzymes as Proteins. By the early 1800s, the proteinaceous nature of enzymes had been recognized. Knowledge of the chemistry of proteins drew heavily on the improving techniques and concepts of organic chemistry in the second half of the 1800s; it culminated in the peptide theory of protein structure, usually credited to FISCHER und HOFMEISTER. However, methods that had permitted the separation and synthesis of small peptides were unequal to the task of purifying enzymes. Indeed, there was no consensus that enzymes were proteins. Then, in 1926, SUMNER crystallized urease from jack bean meal and announced it to be a simple protein. However, WILLSTÄTTER argued that enzymes were not proteins but “colloidal carriers” with “active prosthetic groups.” However, with the conclusive work by NORTHROP *et al.*, who isolated a series of crystalline proteolytic enzymes, beginning with pepsin in 1930, the proteinaceous nature of enzymes was established.

The isolation and characterization of intracellular enzymes was naturally more complicated and, once again, significant improvements were necessary in the separation techniques applicable to proteins before, in the late 1940s, any such enzyme became available in reasonable quantities. Because of the large amounts of accessible starting material and the historical importance of fermentation experiments, most of the first pure intracellular enzymes came from yeast and skeletal muscle. However, as purification methods were improved, the number of enzymes obtained in pure form increased tremendously and still continues to grow.

Methods of protein purification are so sophisticated today that, with sufficient effort, any desired enzyme can probably be purified completely, even though very small amounts will be obtained if the source is poor.

Primary Structure. After the protein nature of enzymes had been accepted, the way was clear for more precise analysis of their composition and structure. Most amino acids had been identified by the early 20th century. The methods of amino acid analysis then available, such as gravimetric analysis or microbiological assay, were quite accurate but very slow and required large amounts of material. The breakthrough came with the work of MOORE and STEIN on ion-exchange chromatography of amino acids, which culminated in 1958 in the introduction of the first automated amino acid analyzer [8].

The more complex question – the arrangement of the constituent amino acids in a given protein, generally referred to as its primary structure – was solved in the late 1940 s. The determination in 1951 of the amino acid sequence of the β-chain of insulin by SANGER and TUPPY [10] demonstrated for the first time that a given protein does indeed have a unique primary structure. The genetic implications of this were enormous. The introduction by EDMAN of the phenyl isothiocyanate degradation of proteins stepwise from the N-terminus, in manual form in 1950 and subsequently automated in 1967 [11], provided the principal chemical method for determining the amino acid sequences of proteins. The primary structures of pancreatic ribonuclease [12] and egg-white lysozyme [13] were published in 1963. Both of these enzymes, simple extracellular proteins, contain about 120 amino acids. The first intracellular enzyme to have its primary structure determined was glyceraldehyde 3-phosphate dehydrogenase [14], which has an amino acid sequence of 330 residues and represents a size (250 – 400 residues) typical of many enzymes. Protein sequencing is increasingly performed by liquid chromatography/mass spectrometry (LC/MS) techniques, and several tools and software packages are now available for protein identification and characterization. The methods of protein sequence analysis are now so well developed that no real practical deterrent exists, other than time or expense, to determination of the amino acid sequence of any polypeptide chain [9].

A more recent fundamental concept called proteome (*prote*in complement to a gen*ome*) will enable researchers to unravel biochemical and physiological mechanisms of complex multivariate diseases at the functional molecular level. A new discipline, *proteomics*, complements physical genome research. Proteomics can be defined as “the qualitative and quantitative comparison of proteomes under different conditions to further unravel biological processes” [15].

Active Site. The fact that enzymes are highly substrate specific and are generally much larger than the substrates on which they act quickly became apparent. The earliest kinetic analyses of enzymatic reactions indicated the formation of transient enzyme – substrate complexes. These observations could be explained easily if the conversion of substrate to product was assumed to occur at a restricted site on an enzyme molecule. This site soon became known as the active center or, as is more common today, the active site.

Particular compounds were found to react with specific amino acid side chains and thus inhibit particular enzymes. This suggested that such side chains might take part in the catalytic mechanisms of these enzymes. An early example was the inhibition of glycolysis or fermentation by iodoacetic acid, which was later recognized as resulting from reaction with a unique cysteine residue of glyceraldehyde 3-phosphate dehydrogenase, which normally carries the substrate in a thioester linkage [16].

Many such group-specific reagents have now been identified as inhibitors of individual enzymes; often they are effective because of the hyper-reactivity of a functionally important side chain in the enzyme's active site. However, a more sophisticated approach to the design of enzyme inhibitors became possible when the reactive group was attached to a substrate; in this way, the specificity of the target enzyme was utilized to achieve selective inhibition of the enzyme [17]. Such active-site-directed inhibitors have acquired major importance not only academically in the study of enzyme mechanisms but also commercially in the search for a rational approach to selective toxicity or chemotherapy.

Three-Dimensional Structure. Chemical studies showed that the active site of an enzyme consists of a constellation of amino acid side chains brought together spatially from different parts of the polypeptide chain. If this three-dimensional structure was disrupted by denaturation, that is, without breaking any covalent bonds, the biological activity of the enzyme was destroyed. In addition, it was found that all the information required for a protein to fold up spontaneously in solution and reproduce its native shape was contained in its primary structure. This was part of the original “central dogma” of molecular biology.

The X-ray crystallography of proteins [18] demonstrated unequivocally that a given protein has a unique three-dimensional structure. Among the basic design principles was the tendency of hydrophobic amino acid side chains to be associated with the hydrophobic interior of the folded molecule, whereas charged side chains were almost exclusively situated on the hydrophilic exterior or surface. The first high-resolution crystallographic analysis of an enzyme, egg-white lysozyme, confirmed these principles and led to the proposal of a detailed mechanism [19]. The active site was located in a cleft in the structure (Fig. 1), which has subsequently proved to be a common feature of active sites. According to this, the enzymatic reaction takes place in a hydrophobic environment, and the successive chemical events involving substrate and protein side chains are not constrained by the ambient conditions of aqueous solution and neutral pH.

[Full View]

1.2. Enzyme Nomenclature

Strict specificity is a distinguishing feature of enzymes, as opposed to other known catalysts. Enzymes occur in myriad forms and catalyze an enormous range of reactions. By the late 1950 s the number of known enzymes had increased so rapidly that their nomenclature was becoming confused or, worse still, misleading because the same enzyme was often known to different workers by different names; in addition, the name frequently conveyed little or nothing about the nature of the reaction catalyzed.

To bring order to this chaotic situation, an International Commission on Enzymes was established in 1956 under the auspices of the International Union of Biochemistry (IUB). Its terms of reference were as follows: “To consider the classification and nomenclature of enzymes and coenzymes, their units of activity and standard methods of assay, together with the symbols used in the description of enzyme kinetics.” The Commission's recommendations have formed the basis of enzyme nomenclature since its first report in 1961 [1].

Responsibility for enzyme nomenclature passed to the Nomenclature Committee of IUB in 1977, which has subsequently published several reports, e.g., [20] and supplements, e.g., [21]; it is expected that further supplements will be published from time to time in the *European Journal of Biochemistry*. The growth in scale can be appreciated from the fact that the 1961 *Report of the Enzyme Commission* listed 712 enzymes, whereas the 1992 version of Enzyme Nomenclature listed 3196. The most recent information about changes or additions to enzyme nomenclature is available at `http://www.chem.qmw.ac.uk/iubmb/`, which also offers also an up-to-date version of the *Enzyme Nomenclature* list.

1.2.1. General Principles of Nomenclature

The accepted system for classification and nomenclature of enzymes embodies three general principles.

The first is that enzyme names, especially those ending in *-ase*, should be used only for single enzymes, i.e., single catalytic entities. They should not be applied to systems containing more than one enzyme.

The second general principle is that an enzyme is named and classified according to the reaction it catalyzes. This refers only to the observed chemical change produced by the enzyme, as expressed in the chemical equation. The mechanism of action is ignored, and intermediate cofactors or prosthetic groups are not normally included in the name. Thus, an enzyme cannot be named systematically until the reaction it catalyzes has been identified properly.

The third general principle is that enzymes are named and classified according to the type of reaction catalyzed, which enables Enzyme Commission (E.C.) code numbers to be assigned to enzymes to facilitate subsequent unambiguous identification. For the purpose of systematic nomenclature, all enzymes in a particular class are considered to catalyze reactions that take place in a given direction, although only the

reverse direction may have been demonstrated experimentally. However, the recommended name for the enzyme may well be based on the presumed direction of the reaction in vivo.

Thus, a given enzyme often has two names, one systematic and the other recommended or trivial. The latter is generally the name in current usage, shorter and more readily applied. After its systematic name and E.C. code number have identified an enzyme, the recommended name can be used without fear of ambiguity. This practice is now generally followed in the literature.

1.2.2. Classification and Numbering of Enzymes

According to the report of the first Enzyme Commission in 1961, enzymes are divided into six main classes according to the type of reaction catalyzed. They are assigned code numbers, prefixed by E.C., which contain four elements separated by points and have the following meaning:

1. the number first indicates to which of the six classes the enzyme belongs,
2. the second indicates the subclass,
3. the third number indicates the sub-subclass, and
4. the fourth is the serial number of the enzyme in its sub-subclass.

The six classes are distinguished in the following manner:

1. *Oxidoreductases*
   This class encompasses all enzymes that catalyze redox reactions. The recommended name is *dehydrogenase* whenever possible, but *reductase* can also be used. *Oxidase* is used only when O_2 is the acceptor for reduction. The systematic name is formed according to *donor : acceptor oxidoreductase.*
2. *Transferases*
   Transferases catalyze the transfer of a specific group, such as methyl, acyl, amino, glycosyl, or phosphate, from one substance to another. The recommended name is normally *acceptor grouptransferase* or *donor grouptransferase.* The systematic name is formed according to *donor : acceptor grouptransferase.*
3. *Hydrolases*
   Hydrolases catalyze the hydrolytic cleavage of C —O, C —N, C —C, and some other bonds. The recommended name often consists simply of the substrate name with the suffix *-ase.* The systematic name always includes *hydrolase.*
4. *Lyases*
   Lyases catalyze the cleavage of C —C, C —O, C —N, and other bonds by elimination. The recommended name is, for example, *decarboxylase, aldolase, dehydratase* (elimination of CO_2, aldehyde, and water, respectively). The systematic name is formed according to *substrate group-lyase.*
5. *Isomerases*
   Isomerases catalyze geometric or structural rearrangements within a molecule. The different types of isomerism lead to the names *racemase, epimerase, isomerase, tautomerase, mutase,* or *cycloisomerase.*
6. *Ligases*
   Ligases catalyze the joining of two molecules, coupled with the hydrolysis of a pyrophosphate bond in ATP or another nucleoside triphosphate. Until 1983, the recommended name often included *synthetase,* but the current recommendation is that names of the type *X – Y ligase* be used instead, to avoid confusion with the name *synthase* (which is not confined to enzymes of class 6). The systematic name is formed according to *X : Y ligase* (ADP-forming).

A few examples will serve to illustrate how this system works. (The full list can be found in *Enzyme Nomenclature* 1992 [20].)

The enzyme alcohol dehydrogenase (recommended name) catalyzes the reaction

$$\text{Alcohol} + \text{NAD}^+ \rightleftharpoons \text{Aldehyde or Ketone} + \text{NADH} + \text{H}^+$$

The enzyme has been assigned E.C. number 1.1.1.1. It may also be called aldehyde reductase, but its systematic name is alcohol: NAD^+ oxidoreductase.

Similarly, the enzyme hexokinase (recommended name), which catalyzes the reaction

$$\text{ATP} + \text{D-Hexose} \rightleftharpoons \text{ADP} + \text{D-Hexose 6-phosphate}$$

has been given the E.C. number 2.7.1.1. It has such other names as glucokinase and hexokinase type IV, and its systematic name is ATP: D-hexose 6-phosphotransferase.

1.3. Structure of Enzymes

Enzymes are proteins (for an exception, see Section The Ribozyme) and, as such, are amenable to structural analysis by the methods of protein chemistry, molecular biology, and molecular biophysics.

1.3.1. Primary Structure

The primary structure of enzymes can be determined by direct chemical methods which, in sensitivity and automation, have reached very high levels of sophistication [9], [22]. However, for many proteins, particularly those with long polypeptide chains, direct sequence analysis would be very time-consuming; others may be available only in very small amounts. In these cases, a more profitable approach is to clone the relevant structural gene and determine its DNA sequence [9], [23], [24]. From this, the amino acid sequence can be inferred. Whenever possible, this sequence should be checked, e.g., for genetic reading frame, against whatever amino acid sequence information is available from direct methods. The recombinant DNA approach is so quick and so powerful, however, that amino acid sequence information about enzymes is growing much more rapidly from this source than from direct chemical analysis [25], [26]. Indeed, the information now available is so large in total that computer data banks are required to store it and make it available for systematic access [27].

1.3.2. Three-Dimensional Structure

The three-dimensional structure of an enzyme can be obtained at high resolution by X-ray crystallography [28] and, for molecules up to ca. 300 amino acids in length, by NMR spectroscopy. By this means, the detailed structures of many enzymes have been determined, and a broad understanding of the principles of protein structure has resulted [29], [30]. Proteins are generally well-ordered; their interiors are well-packed (comparable to other crystalline organic molecules) to produce a hydrophobic core with a dielectric constant similar to that of a hydrocarbon. Proteins vary in the amount of regular secondary structure (α-helix and β-sheet) they contain and can be grouped into four classes according to the combination and packing of these structural features [31]. Although the number of possible combinations of amino acids in a given protein is virtually unlimited, it is estimated that there are not more 1000 different families of folding patterns for protein structures [32].

Despite their close-packed and generally well ordered structure, enzymes are usually not entirely rigid molecules, and some conformational flexibility in solution is widely observed, particularly by NMR spectroscopy [33-37]. These conformational changes may be limited to a molecular “breathing” or flexing of the structure, they may involve various “hinge-bending” motions, or they may extend to more substantial conformational mobility in parts of the polypeptide chain. All such motions, contribute to the mechanisms of enzyme catalysis [2], [38].

As of August 28, 2001, 15 905 3D structures were freely accessible from the website of the Protein Data Bank (`http://www.rcsb.org/pdb/`) [39]. This site also offers several programs for analysis and visualization of protein (and DNA) 3D structures on numerous computer platforms.

1.3.3. Quaternary Structure, Folding, and Domains

Many enzymes consist of more than one polypeptide chain (or subunit), and these must form an aggregate, usually with relatively simple symmetry, before full (or even any) biological activity is conferred (Table 1). The subunits within an oligomer or multimer are often identical or at least limited to a few different types.

Aggregation is generally some form of self-assembly dictated by coherent binding patterns between the subunits, which provide the necessary recognition sites in sorting out the subunits required for assembly [29], [40].

Table 1. Quaternary structures of some typical enzymes

Enzyme	E.C. number [*CAS registry number*]	Source	Number of subunits	Point symmetry: Crystallographic symbol	Point symmetry: Schönflies symbol
Alcohol dehydrogenase	1.1.1.1 [9031-72-5]	horse liver	2	2	C_2
Glutathione reductase	1.6.4.2 [9001-48-3]	human red blood cells	2	2	C_2
Triose phosphate isomerase	5.3.1.1 [9023-78-3]	chicken muscle	2	2	C_2
Lactate dehydrogenase	1.1.1.27 [9001-60-9]	dogfish muscle	4	222	D_2
Glyceraldehyde 3-phosphate dehydrogenase	1.2.1.12 [9001-50-7]	*Bacillus stearothermophilus*	4	222	D_2
Pyruvate kinase	2.7.1.40 [9001-59-6]	cat muscle	4	222	D_2
Aspartate carbamoyltransferase	2.1.3.2 [9012-49-1]	*Escherichia coli*	6 + 6	32	D_3
Dihydrolipoamide acetyltransferase	2.3.1.12 [9032-29-5]	*Escherichia coli*	24	432	0
Dihydrolipoamide acetyltransferase	2.3.1.12 [9032-29-5]	*Bacillus stearothermophilus*	60	532	Y

The complexity of this sorting process in a cell becomes evident from the fact that many intracellular enzymes are dimers or tetramers. Increasingly more complicated structures are being recognized and their design principles analyzed. These range from enzymes with simple cyclic symmetry up to those with the most elaborate cubic point group symmetry, e.g., octahedral and icosahedral [29], [40].

The folding of polypeptide chains, along with their aggregation into ordered structures, is a spontaneous process in solution, and this implies that it is exergonic [39]. However, calculation of the time required for a protein to explore all possible structures during the folding process indicates that the search for the "right" structure cannot be entirely random. Thus, even for a small protein such as bovine pancreatic ribonuclease (124 amino acid residues), such a search might take around 10^{95} years, whereas the experimentally determined time in vivo is a few milliseconds. This dramatic discrepancy led to the concept of *kinetic pathways* during folding. Such pathways have been experimentally explored, and intermediates identified for various proteins. The stable structure of a protein in solution is therefore identified as the lowest free energy form of the kinetically accessible structures [29], [30], [40].

A typical enzyme is not an entity completely folded as a whole, as is evident from the growing catalogue of three-dimensional protein structures determined by X-ray crystallography. On the contrary, enzymes frequently consist of apparently autonomous or semiautonomous folding units, called *domains* (Fig. 2). Sometimes, these may be identified as products of limited proteolysis, i.e., regions of the polypeptide chain that can be excised from the chain with retention of their biological properties. Indeed, this has proved in many instances to be a valuable guide to the actual activity contributed by that part of the enzyme. Classical examples of such functional domains can be found in the study of muscle contraction and antibody-antigen recognition [29], [30].

Figure 2. The domains in glyceraldehyde 3-phosphate dehydrogenase from *Bacillus stearothermophilus* [467]

Reproduced with permission
[Full View]

In other cases, domains are not readily released as biologically active entities, and their existence must be inferred from the three-dimensional structure of the enzyme. Most globular proteins can in fact be subdivided into such regions, which generally have molecular masses of 20 000 or less [29]. The active site of an enzyme is often located at the interface between two such domains as, for example, in the well-known cleft of lysozyme (Fig. 1) or in glutathione reductase. Other domains appear to represent favored folding patterns in the assembly of proteins, but biological activity associated with them can often be inferred from comparison of the structures of related proteins: a typical example is the NAD-binding domain present in dehydrogenases.

Structural domains may be regions of the polypeptide chain that fold independently of each other. Functional domains, as defined above, do indeed fold independently; and individual subunits of oligomeric enzymes appear to fold before association [29], [30], [40], [41].

1.3.4. The Ribozyme

Enzymes are proteins, but the specific involvement of RNA molecules in certain reactions concerned with RNA processing in vivo is worth noting. Until CECH *et al.* [42] and ALTMAN *et al.* [43] published their observations, it was generally accepted knowledge that the major duties in a biological system, namely, to encode information and to catalyze chemical reactions, are neatly split, one being performed by nucleic acids, the other by proteins. With the discovery of special RNAs which store genetic information and can also catalyze reactions on themselves or on other RNAs, this dogma was destroyed [42], [43]. Over the years, it has become evident, that group I and group II introns, catalyze various transesterifications. In cellular systems these reactions facilitate their excision from pre-RNAs and the ligation of flanking exons (self-splicing). In vitro these intron RNAs perform a variety of reactions in cis (i.e., on the same strand of

the RNA genome) and in trans (i.e., on another RNA), such as cleavage and ligation of RNAs, transfer of nucleotides between RNAs, polymerization, and editing-like reactions. These RNAs thus can act as enzymes and are therefore called “ribozymes” [44].

In *Escherichia coli*, tRNA precursors are cleaved by ribonuclease P to generate the correct 5'-ends of the mature tRNA molecules, and the enzyme contains an essential RNA moiety that can function in the absence of the protein. In fact, this RNA moiety fulfills all the criteria of an enzyme [45]. Similarly, the ribosomal RNA of *Tetrahymena thermophila* undergoes self-splicing to perform a highly specific intramolecular catalysis in the removal of an intervening sequence. A truncated version of the intervening sequence, lacking the first 19 nucleotides of the original excised RNA, can then behave as an enzyme in vitro, capable of acting as an RNA polymerase and a sequence-specific ribonuclease under appropriate conditions [46].

The structure of the ribosome's large subunit has since been solved. This largest unique structure established that the ribosome is a ribozyme in which the ribosomal RNA, and not the protein, performs catalytic functions, including the peptidyl transferase reaction that forms the peptide bond [47], [48]. One of the most remarkable findings to emerge from this is that although enzymes composed entirely of protein promote virtually all chemical reactions that occur in living organisms, the protein synthesis reaction that occurs on the ribosome is due to the two-thirds of its mass that is RNA, not the one-third that is protein. In addition to enhancing the understanding of protein synthesis, this work will have significant medical implications, because the ribosome is a major target for antibiotics [49].

Ribozymes also offer an excellent opportunity to compare and contrast the behavior of RNA enzymes with that of protein enzymes. The differences between the RNA and protein enzymes highlight features that are distinct and thus enable a better understanding of each of these classes of biological macromolecules. On the other hand, the features of protein and RNA enzymes that are similar may represent aspects that are fundamental to biological catalysis. Indeed, these studies have suggested that RNA enzymes, like their protein counterparts, can use binding interactions remote from the site of bond transformation to facilitate that transformation [50]. Beyond this, recent results suggest that RNA enzymes are ideally suited for exploration of the energetic origins of this interconnection between binding and catalysis [51]. This use of binding energy provides a natural connection between rate enhancement and specificity, the two hallmarks of biological catalysis. Finally, ribozymes will not only offer new clues about evolution [52], but also offer the potential for specific inactivation of disease-associated mRNAs or viral RNA genomes that, unlike conventional therapeutics, require no knowledge of the structure or function of proteins that target RNAs encode [53].

1.4. Enzymes and Molecular Biology

1.4.1. Biosynthesis of Enzymes

Enzymes are synthesized in cells by the normal machinery of protein synthesis. The structure of any given enzyme is encoded by a structural gene, whose DNA base sequence is transcribed into a messenger RNA, and the mRNA is translated from its triplet code into the amino acid sequence of the desired protein by the ribosomes and associated factors [54], [55]. The enzyme then folds spontaneously into its active conformation. Posttranslational modifications may be required to target an enzyme to its ultimate intracellular or extracellular location.

1.4.2. Enzymes and DNA

For many years, the chemical manipulation of DNA lagged behind that of proteins. The chemical complexity and variety of proteins, with up to 20 different naturally occurring amino acids, served to make them more amenable to increasingly sophisticated methods of analysis. On the other hand, DNA, composed of only four different nucleotides, appeared dauntingly large, with few structural features to make it yield to available methodology.

Paradoxically, this very lack of variety in the nature of the constituent nucleotides of DNA has permitted the revolution in genetic engineering, in which the enzymology of DNA [56] has played a prominent part. For example, the discovery and purification of restriction enzymes enabled DNA to be cleaved selectively into defined fragments; phosphatases and ligases permit the fragments to be rejoined selectively; and DNA polymerases allow DNA to be synthesized and sequenced at astonishing speed, all in vitro [23], [54-56].

2. Catalytic Activity of Enzymes [57, 58, 60]

The theory of enzyme-catalyzed reactions proposed by MICHAELIS and MENTEN in 1913 [61] is based on the assumption that the enzyme (the catalyst, E) and the substrate (the reactant, S) form a complex (ES) by a reversible reaction. The complex is then converted into the product (P) with the reaction rate k_2, when practically no product is present.

$$S + E \underset{k_{-1}}{\overset{k_1}{\leftrightarrows}} ES \xrightarrow{k_2} P + E \tag{2.1}$$

Under commonly used conditions of enzyme activity measurement, c_{ES} can be considered to be sufficiently constant during the observed reaction period (steady-state assumption, BRIGGS and HALDANE [104]):

$$\frac{\mathrm{d}(c_{\mathrm{ES}})}{\mathrm{d}t} = 0 = (k_1 \cdot c_{\mathrm{E}} \cdot c_{\mathrm{S}}) - (k_{-1} \cdot c_{\mathrm{ES}}) - (k_2 \cdot c_{\mathrm{ES}}) \tag{2.2}$$

By using a term for the total concentration of enzyme

$$c_{\mathrm{Et}} = c_{\mathrm{E}} + c_{\mathrm{ES}} \tag{2.3}$$

one obtains

$$0 = k_1 \cdot (c_{\mathrm{Et}} - c_{\mathrm{ES}}) \cdot c_{\mathrm{S}} - (k_{-1} \cdot c_{\mathrm{ES}}) - (k_2 \cdot c_{\mathrm{ES}}) \tag{2.4}$$

or

$$c_{\mathrm{ES}} = \frac{k_1 \cdot c_{\mathrm{Et}} \cdot c_{\mathrm{S}}}{k_{-1} + k_2 + k_1 \cdot c_{\mathrm{S}}} \tag{2.5}$$

By introducing the Michaelis constant K_M

$$K_{\mathrm{M}} = \frac{k_{-1} + k_2}{k_1} \tag{2.6}$$

the reaction rate as a function of c_{ES}

$$v = k_2 \cdot c_{ES} \tag{2.7}$$

and the maximum reaction rate V, which is reached, when all of the enzyme is saturated with substrate ($c_{ES} = c_{Et}$)

$$V = k_2 \cdot c_{Et} \tag{2.8}$$

one obtains the so-called Michaelis–Menten equation

$$v = \frac{V \cdot c_S}{K_M + c_S} \tag{2.9}$$

which shows the dependency of the reaction rate on the substrate concentration (first-order reaction). The plot of this relationship is given in Figure 3.

Figure 3. Reaction rate as a function of substrate concentration (enzyme at constant concentration)

For explanation of symbols, see text
[Full View]

In the case of frequently occurring two-substrate reaction, a similar derivation leads to the formula:

$$v = \frac{V}{1 + \frac{(K_M)_{S1}}{c_{S1}} + \frac{(K_M)_{S2}}{c_{S2}} + \frac{(K_M)_{S1S2}}{c_{S1} \cdot c_{S2}}} \tag{2.10}$$

This is called a second-order reaction. If, however, the concentration of the second substrate is kept at a level many times of the respective Michaelis constant, then the third and fourth term of the denominator are practically zero and the equation is identical with Equation (2.9), allowing the same evaluation as with a one-substrate reaction.

Michaelis Constant. As can be derived from Equation (2.9), the Michaelis constant equals the substrate concentration at half the maximal reaction rate. The value K_M can be obtained by plotting the experimentally measured reaction rate against the various substrate concentrations (Fig. 3). A more convenient way is the plot according to LINEWEAVER and BURK [105], using a reciprocal of the Michaelis – Menten equation

$$\frac{1}{v} = \frac{k_M}{V} \cdot \frac{1}{c_S} + \frac{1}{V} \tag{2.11}$$

A schematic plot is shown in Figure 3. The intersections with abscissa and ordinate allow the determination of the values for K_M and V. For further discussion, see [62]. The Michaelis constant approaches the dissociation constant K_s of the enzyme – substrate complex and is therefore valuable for estimating individual reaction kinetics.

Michaelis constants for enzymes usually range from 10^{-2} to 10^{-5} mol/L; a low K_M indicates a high affinity between enzyme and substrate.

Molar or Molecular Activity (Turnover Number). The efficiency of an enzyme-catalyzed reaction is indicated by the molar activity, formerly called turnover number, which is defined as the number of substrate molecules converted in 1 min by one enzyme molecule under standardized conditions. This can be calculated from the specific activity of a particular enzyme if its molecular mass is known (cf. Section Absorption Photometry). The average molar activity ranges from 10^3 to 10^4; peak values have been measured for acetylcholinesterase (E.C. 3.1.1.7) [9000-81-1] at 1×10^6 and for catalase (E.C. 1.11.1.6) [9001-05-2] at 5×10^6.

2.1. Factors Governing Catalytic Activity [63]

2.1.1. Temperature

The temperature dependence of enzyme-catalyzed reactions exhibits an optimum because the thermodynamic increase of reaction rate (1 in Fig. 5) is followed by a steep drop caused by thermal denaturation of the enzyme (2 in Fig. 5). The optimum is generally between 40 and 60 °C. Some temperature-insensitive enzymes may exhibit an optimum at almost 100 °C. Data on various frequently used enzymes are given in [64]. Figure 5 illustrates temperature dependence [60].

Figure 5. Temperature optimum of enzyme activity
[Full View]

2.1.2. Value of pH

All enzymes have an optimum pH range for activity. The optimum depends not only on pH but also on ionic strength and type of buffer. It may also be influenced by temperature, substrate, and coenzyme concentrations. For most enzymes, the pH optimum lies in the range from 5 to 7. Extreme values of 1.5 and 10.5 have been found for pepsin (E.C. 3.4.23.1) [9004-07-3] and for alkaline phosphatase (E.C. 3.1.3.1) [9001-78-9], respectively. Figure 6 shows some examples [60].

Figure 6. Activity of various enzymes as a function of pH

[Full View]

2.1.3. Activation

Many chemical effectors activate or inhibit the catalytic activity of enzymes. In addition to substrates and coenzymes many enzymes require nonprotein or, in some cases, protein compounds to be fully active. Enzyme activation by many inorganic ions has been adequately described. The activating ion may be involved directly in the reaction by complexing the coenzyme or cosubstrate (e.g., Fe ions bound to flavin or the ATP – Mg complex). In other cases, the ion is part of the enzyme and either acts as a stabilizer for the active conformation (e.g., Zn ions in alkaline phosphatase) or participates directly at the active site (e.g., Mn

ions in isocitrate dehydrogenase (E.C. 1.1.1.42) [9028-48-2] and Zn or Co ions in carboxypeptidases).

2.1.4. Inhibition [65]

In vivo and in vitro inhibition studies of enzymatic reactions contributed important knowledge to various fields of biochemistry. For example, the mechanism of action of many toxic substances and antidotes has been found to affect enzymes directly. In many cases, the importance of these enzymes for metabolism has been revealed. On the other hand, discovery of end-product inhibition elucidated many metabolic pathways. Enzyme inhibition can be either reversible or irreversible. Depending on the type of inhibitory effect, the following mechanisms of enzyme inhibition may be distinguished.

Irreversible Inhibition. An irreversible inhibitor frequently forms a stable compound with the enzyme by covalent bonding with an amino acid residue at the active site. For example, diisopropyl fluorophosphate (DIFP) reacts with a serine residue at the active site of acetylcholinesterase to form an inactive diisopropylphosphoryl enzyme. Alkylating reagents, such as iodoacetamide, inactivate enzymes with mercapto groups at their active sites by modifying cysteine.

Reversible Inhibition. Reversible inhibition, in contrast, is characterized by an equilibrium between enzyme and inhibitor. Several main groups of reversible inhibitory mechanisms can be differentiated.

Competitive Inhibition. The inhibitor competes with the substrate or coenzyme for the binding site on the active center by forming an enzyme-inhibitor complex EI. In most cases, the chemical structure of the inhibitor resembles that of the substrate. Inhibition can be made ineffective by excess substrate, as is the case for inhibition of succinate dehydrogenase (E.C. 1.3.99.1) [9002-02-2] by malonate.

Noncompetitive Inhibition. The inhibitor decreases the catalytic activity of an enzyme without influencing the binding relationship between substrate and enzyme. This means that inhibitor and substrate can bind simultaneously to an enzyme molecule to form ES, EI, or ESI complexes. Noncompetitive inhibition is dependent solely on the inhibitor concentration and is not overcome by high substrate concentration. An example is the blocking of an essential cysteine residue by such heavy metals as copper or mercury.

Uncompetitive Inhibition. The inhibitor reacts only with the intermediary enzyme – substrate complex. An example is the reaction of azide with the oxidized form of cytochrome oxidase (E.C. 1.9.3.1) [9001-16-5]. Lineweaver – Burk plots of the reciprocal initial reaction rate 1/ v_0 versus the reciprocal substrate concentration for these three modes of reversible inhibition are shown in Figures 7 A – C [57]. The inhibitor constant K_I characterizes the inhibiting activity. The respective formulae (reciprocal from according to Lineweaver – Burk [105] are:

Competitive inhibition:

$$\frac{1}{v} = \frac{K_M \cdot \left(1 + \frac{c_I}{K_I}\right)}{V \cdot c_S} + \frac{1}{V} \tag{2.12}$$

Noncompetitive inhibition:

$$\frac{1}{v} = \frac{K_M}{V \cdot c_S} \cdot \left(1 + \frac{c_I}{K_I}\right) + \frac{1}{V} \cdot \left(1 + \frac{c_I}{K_I}\right) \tag{2.13}$$

Uncompetitive inhibition:

$$\frac{1}{v} = \frac{K_m}{V \cdot c_S} + \frac{1 + \frac{c_I}{K_I}}{V} \tag{2.14}$$

For details, see [62].

Figure 7. Lineweaver – Burk graphs of reversibly inhibited enzyme reactions

A) Competitive inhibition; B) Noncompetitive inhibition; C) Uncompetitive inhibition

– – –: Uninhibited reaction
[Full View]

Substrate Inhibition. High concentration of substrate (or coenzyme) may decrease the catalytic activity of an enzyme. Examples are the action of ATP on phosphofructokinase (E.C. 2.7.1.11) [9001-80-3] or of urea on urease (E.C. 3.5.1.5) [9002-13-5]. The Lineweaver – Burk plot [105] is given in Figure 7.

Figure 8. Lineweaver – Burk graph of a substrate inhibition of an enzyme
[Full View]

End-Product Inhibition. In many multienzyme systems, the end product of the reaction sequence may act as a specific inhibitor of an enzyme at or near the beginning of the sequence. The result is that the rate of the entire sequence of reactions is determined by the steady-state concentration of the end product (Fig. 9). This type of inhibition is also called *feedback inhibition* or *retroinhibition.*

Figure 9. Natural mechanisms for regulating enzyme activity
[Full View]

2.1.5. Allostery [66]

Cosubstrates with a central role in metabolism, such as acetyl-CoA, ATP, or AMP, may also influence the rate of reaction sequences by allosteric regulation. For example, phosphofructokinase, the first enzyme in the energy-supplying Embden – Meyerhof – Parnass pathway, is inhibited by a high concentration of ATP (i.e., positive energy balance). A high concentration of AMP, on the other hand, (i.e., energy deficiency) terminates this inhibition. Allosterically regulated enzymes have a quaternary structure and are composed of two or more structurally similar or identical subunits (protomers), each with a binding site for the substrate and another independent binding site for the allosteric effector. The binding of the effector modifies the conformation of the subunit and its active center, which then affects the conformation and hence the catalytic activity of the entire molecule. The cooperation of substrate and effector regulates the overall catalytic activity of the enzyme depending on the concentration of metabolite.

Allosteric enzymes usually do not show the classical Michaelis – Menten kinetic relationship of c_s, V, and K_M. Many allosteric enzymes give a sigmoid plot of initial rate vs. substrate concentration rather than the hyperbolic plots predicted by the Michaelis – Menten equation. The shape of the curve is characteristically changed by an allosteric activator (positive cooperativity) or an allosteric inhibitor (negative cooperativity), as shown in Figure 10.

Figure 10. Activity of an allosteric enzyme as a function of substrate concentration in absence and presence of an allosteric activator or inhibitor
[Full View]

This sigmoidal curve implies that within a certain range of substrate concentration, the enzyme is able to respond to small concentration changes by great activity changes.

2.1.6. Biogenic Regulation of Activity

In principle, enzyme activity may also be controlled by regulating the amount of enzyme in the cell. This can be accomplished by regulating the biosynthesis of individual enzymes or of several functionally related enzymes by induction or repression, or by specific attack of proteolytic enzymes (Fig. 9).

Chymotrypsin (E.C. 3.4.21.1) [9004-07-3], for example, is synthesized as inactive zymogen and converted to the active enzyme by trypsin (E.C. 3.4.21.4) [9002-07-7], a typical protease. A large number of natural protease inhibitors have been isolated and characterized. They act as protease antagonists and are capable of selectively affecting many proteolytic reactions. These proteinase inhibitors are proteins with molecular masses of 5000 – 25 000; they inhibit proteases by specific complex formation [67].

Another important regulation mechanism is the modification of activity by phosphorylation and dephosphorylation, which allows quick adaptation to changing environmental conditions. For example, this takes place with hydroxymethylglutaryl-CoA reductase (NADPH) (E.C. 1.1.1.34), which is phosphorylated by [hydroxymethylglutaryl-CoA reductase (NADPH)] kinase (E.C. 2.7.1.109) [106] and dephosphorylated by [hydroxymethylglutaryl-CoA reductase (NADPH)] phosphatase (E.C. 3.1.3.47) [107]. In addition, this enzyme is regulated at the protein synthesis level and by controlled degradation.

2.2. Enzyme Assays

2.2.1. Reaction Rate as a Measure of Catalytic Activity

As biological catalysts, enzymes increase the rate of a reaction or permit it to proceed. Therefore, the conversion rate of substrates, v, is measured to determine the catalytic activity. The respective formulae for enzyme kinetics are given in Equations (2.9) and (2.10).

If in Equation (2.9) the substrate concentration is kept at a level considerably above the Michaelis constant ($c_S \gg K_M$), then all of the enzyme is saturated with substrate and the reaction proceeds with the constant and the maximum rate $v = V$ (zero order reaction). Consequently, catalytic activity is linearly dependent on the amount of enzyme used. This situation is attempted to be reached in enzyme activity measurements.

2.2.2. Definition of Units

Originally, units were defined by the investigator who first discovered and described an enzyme. Therefore, in the older literature, enzyme activity was expressed in arbitrary units, e.g., changes in absorbance, increase of reducing groups, amount of converted substrate expressed in milligrams or micromoles. These parameters were related to various time units, such as 1 min, 30 min, or 1 h.

To obtain standardized values for each enzyme, in 1961 the Enzyme Commission of the International Union of Biochemistry defined the *International Unit* U as the activity of an enzyme which, under optimized standard conditions, catalyzes the conversion of 1 µmol of substrate per minute. With respect to basic SI units, the Expert Panel on Quantities and Units (EPQU) of the International Federation of Clinical Chemists (IFCC) and the Commission on Quantities and Units in Clinical Chemistry (CQUCC) of IUPAC defined the base unit *katal* as the catalytic amount of any enzyme that catalyzes a reaction (conversion) rate of 1 mol of substrate per second in an assay system [68]. This unit, however, is not in common use.

The temperature must be stated for each assay. As a general rule, the rate of enzymatically catalyzed

reactions is about doubled by a temperature increase of 10 °C in the range of 0 – 40 °C. The temperature must be controlled precisely and kept constant to achieve reproducible results [63].

However, for practical reasons, many enzyme reactions cannot be monitored by measuring the stoichiometric amount of substrate consumed or product formed. Therefore, the catalytic activity of a particular enzyme may be impossible to express in International Units.

The definition of units for most enzymes used in molecular biology is rather arbitrary. For example, the unit of a restriction endonuclease (E.C. 3.1.21.3 – 5), is defined as the catalytic activity of the enzyme that yields a typical cleavage pattern, detectable after electrophoresis, with a precise amount (usually 1 µg) of a particular DNA under defined incubation conditions [69], [70]. Other parameters that define the activity of such enzymes are the degradation of a nucleic acid or the incorporation of nucleotides into a nucleic acid, expressed in micrograms, nanomoles, absorbance units, or number of base pairs. For practical reasons, different time periods such as 1, 10, 30, or 60 min, may be chosen as references.

2.2.3. Absorption Photometry [71]

Basic Considerations. Because of its simple technique and reliable, reasonably priced instruments, photometry is today one of the preferred methods of enzyme assay. It can be carried out most quickly and conveniently when the substrate or the product is colored or absorbs light in the ultraviolet region because the rate of appearance or disappearance of a light-absorbing product or substrate can be followed with a spectrophotometer.

According to the Bouguer – Lambert – Beer law, which is valid for very dilute solutions, the following relationship exists between absorbance *A* and concentration:

$$A = \log \frac{I_0}{I} = \varepsilon \cdot c \cdot d \tag{2.15}$$

and

$$c = \frac{A}{\varepsilon \cdot d} \tag{2.16}$$

where *c* is the concentration in millimoles per liter, ε the millimolar absorption coefficient in liters per mole and per millimeter, and *d* the path length in millimeters.

The catalytic activity *z* then corresponds to the absorbance change per minute.

$$z = \frac{\Delta A \cdot V \cdot 1000}{\varepsilon \cdot d \cdot \Delta t} \tag{2.17}$$

where *V* is the assay volume in liters and *t* the time in minutes. The unit of *z* is then micromoles per minute and corresponds to the definition of the International Unit U given in the previous section.

Example 1: Assay of Lactate Dehydrogenase (*LDH*).

In the reaction catalyzed by LDH (E.C. 1.1.1.27) [9001-60-9], hydrogen is transferred from NADH to pyruvate, to yield L-lactate and NAD [72]:

$$\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{L-Lactate} + \text{NAD}^+ \tag{2.18}$$

The reduced coenzyme NADH absorbs at 340 nm, whereas the oxidized form NAD, lactate, and pyruvate do not. Thus the progress of Reaction (2.18) can be followed by measuring the decrease in light absorption at

340 nm with a mercury line photometer emitting at 334 or 365 nm. The enzyme can also be measured by monitoring the reverse reaction under slightly alkaline conditions. However, the reverse reaction is much slower than the reaction starting with pyruvate [73].

The principle of the optical assay may also be used to follow an enzymatic reaction in which neither the substrate nor the product has any characteristic light absorption maxima. In that case, the reaction is coupled to some other enzymatic reaction which can be followed easily by photometry. The activity of the nonabsorbing enzyme system can then be measured if the enzyme considered is made the rate-determining component by appropriate choice of assay conditions.

Example 2: Assay of Pyruvate Kinase (*PK*). The reaction between phosphoenolpyruvate and ADP yields pyruvate and ATP by transfer of a phosphate group; it is catalyzed by pyruvate kinase (E.C. 2.7.1.40) [9001-59-6]:

$$\text{Phosphoenolpyruvate} + \text{ADP} \rightarrow \text{Pyruvate} + \text{ATP} \tag{2.19}$$

This reaction is easily measured when a large excess of LDH and NADH is added to the system, which couples Reactions (2.19) and (2.18) [74]. The formation of pyruvate in Reaction (2.19) is followed by the very rapid reduction of pyruvate to lactate in Reaction (2.18). For each molecule of pyruvate formed and reduced, one molecule of NADH is oxidized to NAD, causing a decrease in light absorption at 340 nm.

The catalytic activity of enzymes such as phosphatases [75], whose natural substrates do not have suitable spectral properties, can be determined by using a colorless synthetic substrate, which is split enzymatically to yield a colored product.

Example 3: Assay of Phosphatase. For the assay of phosphatases, glycosidases, and several other hydrolases, colorless 4-nitrophenyl compounds are incubated, and 4-nitrophenolate is formed under alkaline conditions with a characteristic maximum between 400 and 420 nm. In this way, the catalytic activity of such enzymes can be measured conveniently at this wavelength:

$$\text{4-Nitrophenyl phosphate} + H_2O \rightarrow \text{4-Nitrophenol} + \text{Phosphate} \tag{2.20}$$

$$\text{4-Nitrophenol} + OH^- \rightarrow \text{4-Nitrophenolate} \tag{2.21}$$

Another principle involves the absorption of a colored metabolite formed directly or indirectly, by the action of the enzyme being analyzed. Again, the activity of the enzyme can be determined only if it is made the rate-determining component by proper choice of conditions.

Example 4: Assay of Glycerol Phosphate Oxidase. Among the class of oxidoreductases utilizing O_2 as the sole final electron acceptor, many enzymes exist that generate H_2O_2 during oxidation of their individual substrates [76]. Highly sensitive and accurate colorimetric assays of H_2O_2 have been developed during the last two decades [77]; in one system, phenol gives a purple color with 4-aminoantipyrine in the presence of oxidizing agents. Therefore, this color reaction can be used for colorimetric determination of H_2O_2-generating enzyme reactions with peroxidase as oxidation catalyst and indicator enzyme.

Although this principle is used predominantly to determine metabolites in body fluids, it is often employed in the assay of such enzymes as glycerol phosphate oxidase (E.C. 1.1.3.21) or glucose oxidase (E.C. 1.1.3.4) [9001-37-0].

The catalytic activity of the first is determined according to the following reaction sequence:

$$2\,\text{L-}\alpha\text{-Glycerol phosphate} + 2\,O_2 \rightarrow 2\,\text{Dihydroxyacetone phosphate} + 2\,H_2O_2 \quad (2.22)$$

$$2\,H_2O_2 + 4\text{-Aminoantipyrine} + \text{Phenol} \rightarrow \text{Quinonimine dye} + 4\,H_2O \quad (2.23)$$

The broad absorption maximum of the quinonimine dye is centered around 500 nm, with an absorption coefficient of about 13×10^2 L mol^{-1} mm^{-1}. The increase in absorbance per minute at 500 nm is measured to determine the activity of glycerol phosphate oxidase.

2.2.4. Fluorometry [78]

The fluorometric method is rarely used for determining the catalytic activity of raw or purified enzyme preparations. Because of its high sensitivity, it permits the assay of small amounts of enzymes in organs or tissue sections [79]. For example, systems that depend on NAD and NADP can be measured by fluorometry; the reduced pyridine coenzymes exhibit a fluorescence of low intensity. To enhance sensitivity, the oxidized form is treated with alkali, to yield strongly fluorescing compounds; in addition, selective filters must be used. The overall sensitivity of this method is a thousand times that of absorption photometry.

2.2.5. Luminometry [80]

Luminometry uses fluorescence, phosphorescence, and chemiluminescence as detector systems. Chemiluminescence observed in living organisms is termed bioluminescence. Bioluminescence is catalyzed by enzymes called luciferases, whose substrates, known as luciferins, are converted to light-emitting products.

In luminometry, the number of photons emitted by the reaction system per unit time is measured with specially designed instruments called luminometers; they are based on single photon counting detectors, usually photomultiplier tubes.

An example is the reaction catalyzed by the luciferase from *Photinus pyralis*, *Photinus*-luciferin 4-monooxygenase (ATP-hydrolyzing) (E.C. 1.13.12.7) [61970-00-1]:

$$\text{ATP} + \text{D-Luciferin} + O_2 \rightarrow \text{Oxyluciferin} + \text{AMP} + \text{pp} + CO_2 + 0.9\,h\nu \quad (2.24)$$

In this reaction, ATP is consumed as a substrate, and photons at a wavelength of 562 nm are emitted. The quantum yield is 0.9 einstein per mole of luciferin, i.e., for one ATP molecule consumed, approximately one photon is emitted. This reaction is therefore suitable for the assay of ATP and, hence, of enzymes that catalyze ATP-consuming or ATP-producing reactions.

To monitor enzyme activity with the aid of firefly bioluminescence, the light intensity must increase linearly for several minutes and must be strictly proportional to the catalytic activity of the enzyme. Such measuring conditions have been realized for determination of the catalytic activity of creatine kinase (E.C. 2.7.3.2) [9001-15-4]:

$$\text{Creatine phosphate} + \text{ADP} \rightarrow \text{Creatine} + \text{ATP} \quad (2.25)$$

Other reactions that depend on NAD(P) can be followed by using the bioluminescence from lucibacteria.

2.2.6. Radiometry

When radioactively labeled substrates are used, the activities of some enzymes can be determined with high sensitivity. This technique is widely employed in the field of molecular biology to monitor (1) the incorporation of radioactively labeled nucleotides into acid-insoluble nucleic acids or polynucleotides (DNA and RNA polymerases), (2) the decomposition of radioactively labeled DNA (exonuclease III), (3) the

transfer of a radioactively labeled phosphate group from γ-^{32}P-ATP [2964-07-0] to the 5′-hydroxyl end of a polynucleotide (polynucleotide kinase), or (4) the exchange of radioactively labeled pyrophosphate on a carrier matrix (T_4 DNA ligase). The most common isotopes for labeling are ^{32}P, ^{14}C, ^{3}H, and to a minor degree, ^{35}S.

In experiments with radioactively labeled compounds, special safety and legal regulations must be observed. In some determinations, however, the amounts of radioactive material needed are below the limits regulated by law.

2.2.7. Potentiometry [81]

A pH-sensitive glass electrode can be used to measure reactions in which protons are produced or consumed. For this purpose, the pH is kept constant by countertitration, and the consumption of acid or base required to do this is measured. The electrode controls an automatic titrator, and this concept is the *pH-stat* technique described by BÜCHER [82]. A typical example is the determination of the catalytic activity of lipase (E.C. 3.1.1.3) [9001-62-1] [83]. A fat (triglyceride) is hydrolyzed by this enzyme, and the fatty acid formed is neutralized by countertitration with NaOH in a pH-stat mode:

$$\text{Triglyceride} + H_2O \rightarrow \text{Diglyceride} + \text{Fatty acid} \qquad (2.26)$$

The substrate, olive oil, is incubated with the diluted sample containing lipase, and the mixture is titrated at constant pH. A recorder plots the consumption of NaOH vs. time, and the resulting slope correlates with catalytic activity. Other examples are the assay of papain (E.C. 3.4.22.2) [9001-73-4] and glucose oxidase (E.C. 1.1.3.4.) [9001-37-0].

2.2.8. Conductometry

In principle, all enzymatic reactions that lead to a change in overall ionic mobility can be measured by conductometry. In this way, the elastolytic activity of elastase (E.C. 3.4.21.36) by using unmodified elastin as substrate has been determined [84]. Other applications have also been described [85]. In this reaction, protons are liberated by cleavage of peptide bonds.

2.2.9. Calorimetry

Many enzymatic reactions evolve heat; therefore, some interest in calorimetric (enthalpimetric) methods has developed. In a suitable experimental arrangement, a temperature sensor serves as a device for measuring the catalytic activity of the enzyme. A new area of analytical chemistry has developed from this approach. Previously called microcalorimetry, it is now commonly known as enthalpimetry [86]. The method is used mainly in research.

2.2.10. Polarimetry

Polarimetry is rarely used, partly because of the inconvenience involved. However, it is required in determining the catalytic activity of mutarotase (E.C. 5.1.3.3.) [9031-76-9], which catalyzes the equilibrium between α- and β-glucose [87].

2.2.11. Manometry

Manometry is one of the classical methods in biochemistry. It is no longer used for routine assay of enzymes. Formerly, the catalytic activity of glucose oxidase [88], arginase (E.C. 3.5.3.1) [9000-96-8] [89], and other enzymes was determined by this method.

2.2.12. Viscosimetry

Viscosimetry has been practically abandoned for enzyme assays. Formerly, e.g., cellulase (E.C. 3.2.1.4) [9012-54-8] activity has been determined by the change of viscosity per unit time [90]. Nowadays the cellulase assay is performed with a colorimetric reaction [108]:

$$\text{Cellulose} \rightarrow \text{Oligosaccharide} + n\,\text{Glucose} \rightarrow \text{Red dye} \qquad (2.27)$$

2.2.13. Turbidimetry

The turbidimetric method can be adapted for different enzyme assays [109]. As an example, lysozyme (muramidase, E.C. 3.2.1.17) cleaves bacterial cell walls. A standard substrate suspension (dried germs of *Micrococcus luteus)* is used. The decrease of absorbancy is measured at 450 nm and 25 °C.

2.2.14. Immobilized Enzymes [91]

Immobilized enzymes are used in analytical chemistry and as catalysts for the production of chemicals, pharmaceuticals, and food (Section Immobilization). They also serve as simple and well-defined models for studying membrane-bound enzymes.

Because of their particular structure, immobilized enzymes require specific assays. In addition to requiring optimal conditions different from those of soluble enzymes, particle size, particle-size distribution, mechanical and chemical structure, stability and structure of the matrix, and the catalytic activity used for immobilization must be considered.

At least two different assay procedures are used for insoluble enzymes: one employs a stirred suspension in a vessel; the other, a packed bed or a column reactor. The conditions of such assay are very close to those used in industrial applications. Enzyme activity can be assayed continuously or batchwise.

Conductometry, potentiometry, and polarimetry are better suited to detection than photometry, because they allow the reaction to be followed directly, without the need for additional indicator enzymes, coenzymes, or second substrates. An example is the assay of immobilized penicillin amidase (E.C. 3.5.1.11) [9014-06-6] [92]:

$$\text{Penicillin G} + H_2O \rightarrow \text{6-Aminopenicillanate} + \text{Phenyl acetate} + H^+ \tag{2.28}$$

2.2.15. Electrophoresis

Electrophoresis is an indispensable tool for determining the catalytic activity of nucleases, especially restriction endonucleases. It is also used for other important enzymes in genetic engineering, e.g., DNA methylases. Restriction enzymes catalyze the specific cleavage of DNA, e.g., that of *Escherichia coli* phage λ DNA, which is a typical substrate in genetic engineering (see Chap. Nonindustrial Enzyme Usage). The DNA is split into smaller fragments of defined lengths. Because the negative charge per base pair is the same for all fragments, these can be separated according to length. The products of cleavage can be separated from intact or incompletely split molecules by electrophoresis under conditions that are carefully optimized for each specific enzyme – substrate reaction. Electrophoresis is usually performed with high-quality agarose gels as carrier material. Each resolution problem requires a specific agarose concentration, e.g., a relatively low concentration (0.5 g per 100 mL) for large fragments and a relatively high concentration (1.6 – 2 g per 100 mL) for small fragments. When very small fragments must be separated, polyacrylamide gels may be used as an alternative carrier material. Separated DNA fragments are visualized by staining with the fluorescent dye ethidium bromide [1239-45-8].

The fragments can be labeled by staining the gel in a separate tank after completion of electrophoresis or, more easily, by electrophoresis in the presence of the dye in the gel and buffer (e.g., at 1 µg/mL). When the gel is illuminated with long-wavelength UV light (e.g., at 366 nm), the separated fragments become visible and can be photographed.

To calculate enzyme activity, the minimum amount of enzyme must be estimated which converts a given substrate completely to the fragment pattern typical for that enzyme. For practical reasons, this amount is divided by the volume of the enzyme solution.

As an example, electrophoretic assay of the restriction enzyme *Hin*dIII is described briefly (Fig. 11) [69].

Figure 11. Determination of the catalytic activity of *Hin*dIII on λ DNA

a) λ DNA without enzyme; b – d) 1, 2, and 3 µL, respectively, 1 : 30 dilution; e – g) 1, 2, and 3 µL, respectively, 1 : 20 dilution; h – j) 1, 2, and 3 µL, respectively, 1 : 10 dilution
[Full View]

Definition of unit:

one unit is the catalytic activity of *Hin*dIII, which completely splits 1 µg of λ DNA in a total volume of 0.025 mL. The reaction is terminated after 60 min incubation at 37 °C in 0.025 mL of a defined buffer mixture.

Assay: different volumes (1 – 3 µL) of several enzyme dilutions (1 : 10, 1 : 20, 1 : 30) are incubated with 1 µg of λ DNA in a total volume of 0.025 mL. The reaction is terminated after 60 min by cooling with ice and adding 0.015 mL of a stop solution; the mixture (0.02 mL) is then placed in the slots of an agarose gel.

Agarose gel:

the gel consists of 1 g of agarose per 100 mL and 1 mg of ethidium bromide per liter. The gel dimensions are 200×200 mm; total volume is 250 mL; and slots of 1×7 mm are prepared with a comb.

Electrophoresis: the apparatus is designed for submarine electrophoresis (2 h at 100 V). The buffer system is tris(hydroxymethyl)aminomethane – acetate, 40 mmol/L, and disodium ethylenediamine-tetraacetate, 2 mmol/L; pH 8.2. The buffer contains 1 mg of ethidium bromide per liter.

Detection: the gel is illuminated directly after electrophoresis with long-wavelength UV light (366 nm) and photographed (Polaroid CU 5/film type 107); the amount of enzyme is estimated at which the complete typical fragment pattern is obtained [e.g., slot (c) in Fig. 11]. The activity is calculated according to

$$\text{Activity} = \frac{\text{Dilution}}{\text{Sample volume, mL}} \times \frac{\text{Units}}{\text{Volume, mL}} \tag{2.29}$$

(of original enzyme solution) In the example, complete digestion was obtained with a minimum of 0.003 mL at 1 : 30 dilution of the original enzyme solution, resulting in an activity of 10 000 U/mL.

2.3. Quality Evaluation of Enzyme Preparations

2.3.1. Quality Criteria

The quality of enzyme preparations is characterized by activity, purity, stability, formulation, and packaging. These parameters depend on each other, but the formulation and packaging are easy to control and keep constant. The other parameters influence each other in such a way that quality is considered to be a function of activity, purity, and stability [93].

2.3.2. Specific Activity

One of the most important quality criteria of an enzyme preparation is its *specific activity*, i.e., the catalytic activity related to its protein content. Specific activity is usually expressed as units per milligram or, for less purified products, units per gram (see Section Definition of Units).

Specific activity data can be evaluated correctly only if the specific activity can be compared with that of a highly purified enzyme of the same origin. For this purpose, catalytic activities must be measured under identical conditions including the determination of protein.

2.3.3. Protein Determination

Since protein content is the most important reference point for determination of the specific activity of an enzyme preparation, several methods of protein determination are briefly mentioned in the following paragraphs [94]. All of these procedures are based on different principles and depend on the amino acid composition of the enzyme proteins. They will, therefore, yield different values.

Ultraviolet Absorption. Because of their content of aromatic amino acids, proteins exhibit an absorption maximum at 270 – 280 nm. For many pure proteins, reference values have been established for the 280-nm absorbance of a solution containing 10 mg/mL ($A_{280}^{1\,\%}$). WARBURG and CHRISTIAN found a formula which accounts for the nucleic acid content [95]. For greater precision, absorbance is also measured at shorter wavelengths, e.g., 235 nm [96].

Biuret Method [97]. The reaction of peptide bonds with copper ions in an alkaline solution yields a purple complex which can be determined photometrically. The intensity is a linear function of protein concentration.

BCA Method [110]. The BCA method of the company Pierce is used for many protein samples. It combines the biuret method with the features of BCA:

$$\text{Protein} + \text{Cu}^{++} + \text{Bicinchoninic acid} \rightarrow \text{Red dye}\,(\text{Cu}^{+}\,\text{complex}) \qquad (2.30)$$

The complex allows the spectrophotometric quantitation of the protein in aqueous solutions.

Lowry Method [98]. The *Lowry* method combines the biuret reaction of proteins with reduction of the *Folin–Ciocalteu* phenol reagent (phosphomolybdic – phosphotungstic acid) by tyrosine and tryptophan residues. The reduction is promoted by the copper – protein complex. This method is very sensitive, but it is affected by many other compounds. The method has been modified to overcome these problems and to obtain a linear relationship between absorbance and protein content.

Protein-Dye Binding. Attempts have been made to determine protein concentration by using dyes. The method published by BRADFORD now predominates [99]. It is based on the shift of the absorption maximum of Coomassie Brilliant Blue G 250 [6104-58-1] from 465 to 595 nm, which occurs when the dye binds to the protein.

Kjeldahl Analysis. Before colorimetric procedures were established, protein concentration was calculated from nitrogen content by using an empirical factor [97].

2.3.4. Contaminating Activities

The content of contaminating activities, that is, the presence of other enzymes in the original material, is an important quality criterion for enzymes. This is usually related to the activity of the main enzyme and expressed in percent. Since the absolute amount is often very small, it cannot be expressed as protein mass (in milligrams) and, thus, does not influence the overall specific activity of the enzyme preparation. For example, lactate dehydrogenase from rabbit muscle has a specific activity of 500 U/mg and contains 0.001 % pyruvate kinase. Even if the content of pyruvate kinase increased tenfold to 0.01 %, the corresponding change in specific activity could not be measured. However, this contaminating activity is so high that such an enzyme preparation is useless for the determination of pyruvate kinase in blood.

Depending on the special applications of an enzyme, different impurities must be determined. For example, enzymes used in genetic engineering all act on a common substrate, nucleic acid; therefore, they must be free from impurities that also act on that substrate, such as specific or unspecific nucleases or phosphatases. Traces of unspecific endodeoxyribonucleases, for example, are detected routinely by incubating 10 – 100 U of an enzyme for a prolonged period (e.g., 16 h) with a susceptible substrate such as the supercoiled form of a plasmid DNA, e.g., pBR322. A minimum of 50 units should not influence the structure of that substrate, whereas another application may require that only 10 units do not change substrate structure. Such impurities are usually detected by electrophoresis (see Section Electrophoresis) or by radiometry (see Section Radiometry).

2.3.5. Electrophoretic Purity

Electrophoresis is important in the evaluation of purity because of its sensitivity (detection of less than 50 µg/mL contaminating protein is possible). It is far inferior to the determination of contaminating activities. Furthermore, enzymatically inactive proteins usually do not interfere with enzymatic analyses. Electrophoresis gained importance when isoenzymes had to be analyzed which could not be distinguished by their catalytic function but only by physical properties such as electric charge. It is an indispensable tool for the identification of lactate dehydrogenase isoenzymes.

Electrophoresis is also used in the isolation of various enzymes of RNA, DNA, and protein biosynthesis. For this purpose, the introduction of disc electrophoresis on polyacrylamide gels and the use of dodecyl sulfate for the separation of enzyme complexes became valuable tools [100]. The system developed by LAEMMLI [101] is widely used and exhibits very high sensitivity, especially if gradient gels are employed [102]. The sensitivity of the method has been enhanced considerably by silver staining [103].

Electrophoresis with 2-dimensional gels (2D PAGE) and isoelectric focussing (IEF), which separates the proteins according to their isoelectric points are commonly used methods [111], [112]. The Phast-system (Pharmacia) [113] and the electroblotting of biomolecules is applied for automatic gel electrophoresis. It consists in the transfer of electrophoretically separated proteins from the polyacrylamide matrix onto a “protein absorbing” membrane in an electrical field.

2.3.6. High-Performance Liquid Chromatography [111]

Since the 1980s the method has gained popularity for proteins. HPLC-assays are used to test enzymes for purity or to obtain information about isoenzymes. The pattern of the peaks is evaluated. Examples are peroxidase (E.C. 1.11.1.7), alkaline phosphatase (E.C. 3.1.3.1) and catalase (E.C. 1.1.1.6).

2.3.7. Performance Test

For many applications, partially purified enzyme preparations can be used, provided they do not contain any interfering contaminating activities. They are less costly and, therefore, preferred to highly purified products. However, they may contain unknown byproducts that can interfere with enzymatic analyses, for example. To avoid such problems, a performance test should be carried out. Examples are the determination of glucose with glucose oxidase and peroxidase (E.C. 1.11.1.7) [9003-99-0] or the determination of glycerol with glycerokinase (E.C. 2.7.1.30) [9030-66-4].

For some enzymes used in molecular biology, the determination of activity is not directly correlated to their application. In such cases, even highly purified enzymes must be analyzed for proper function in a typical performance experiment. An example is T_4 DNA ligase (E.C. 6.5.1.1) [9015-85-4] which functions properly by joining together fragments created by the action of a restriction endonuclease; in addition, the joined fragments can be recleaved by the same restriction endonuclease.

2.3.8. Amino Acid Analysis and Protein Sequence Analysis

Both methods are routinely used to estimate the amount and to determine the composition of enzymes. For amino acid analysis, the protein is first cleaved by complete hydrolysis (enzymatically or chemically). Then the released amino acids are assayed by quantitative chromatography. The amino acids require derivatization to improve their chromatographic behavior or their detectability. Although this is a laborious method, it is used frequently [115].

Sometimes it is necessary to characterize the enzyme sequence in detail, e.g., to check for purity this way. A useful procedure is the Edman degradation [116], [117]. With this method, the *N*-terminal amino acid is cleaved from a peptide or a protein, derivatized with phenylisothiocyanate and identified. Then the reactions are repeated with the next amino acid. Today, many instruments perform the Edman degradation automatically.

2.3.9. Stability [93]

A very important factor in the application of enzymes is their stability in concentrated or dilute form and after mixing with other substances. This applies to the manufacture of products for pharmaceutical purposes, food chemistry, or enzymatic analysis. Some enzymes can be stabilized by adding glycerol (50 vol %),

ammonium sulfate (ca. 3.2 mol/L), or sodium chloride (3 mol/L) to their aqueous solution. Furthermore, many enzymes can be kept in lyophilized form for a long period of time in the presence of stabilizers such as salts, preservatives, inert proteins (predominantly bovine serum albumin), or carbohydrates.

Most enzymes used in analysis are stored at ca. 4 °C; solutions of restriction endonucleases must be kept at – 20 °C or lower to maintain catalytic activity. To avoid degradation by moisture, the chilled enzyme preparation must be warmed before opening. Freezing and thawing may, in some cases, impair the activity of enzymes. Contamination by heavy metals or oxidants often inactivates enzymes, for example, by blocking mercapto groups. The activity of metalloenzymes or metal-dependent enzymes may be reduced by complexing agents such as ethylenediaminetetraacetate.

Especially for applications in commercial test kits some enzymes are modified by immobilization [118], for example, by covalent crosslinking with biopolymers like cellulose or dextrane. This improves the stability in solutions and/or the heat resistance.

2.3.10. Formulation of Enzyme Preparations

An enzyme preparation should be formulated according to its application. For analytical purposes, it should be easy to pipette and — if possible — free of stabilizers and preservatives that might impair its function. For example, glutamate dehydrogenase (E.C. 1.4.1.3) [9029-12-3] must not contain any traces of ammonia if it is to be used in the enzymatic determination of urea or ammonium.

In reagent kits employed for enzymatic analysis in clinical laboratories or for food analysis, the enzyme may be used preferably in lyophilized form. Compared to enzyme solutions, the solid material is in some cases easier to mix with other solid components and stable for a longer period of time, even at slightly elevated temperature. When immobilized enzymes are to be used in columns, their particle size must ensure fast flow.

Packaging. Careful selection of packaging materials is very important for handling enzymes. Bottles and stoppers used for lyophilized enzymes must be absolutely tight to prevent access of moisture. Glass or plastic bottles as well as stoppers (rubber or plastic) should not release any traces of heavy metals or other enzyme-inactivating substances into the enzyme solution or suspension. In some cases, enzymes must be protected from light and packaged in brown glass bottles.

3. General Production Methods

3.1. Microbial Production

Use of an aerobic submerged culture in a stirred-tank reactor is the typical industrial process for enzyme production involving a microorganism that produces mostly an extracellular enzyme. This section concentrates on the typical process, with only short references to variations. Figure 12 shows the unit operations of the production process, and basic information can be found under → Biotechnology and in handbooks on microbiological principles and methods [119-121]. This section is concerned with fermentation itself, and three elements — the organism, the equipment, and the protocol for fermentation — are discussed. These elements must be arranged in the most effective way possible to realize economically optimal results in industrial processes. Optimization of biotechnological processes is a multidisciplinary effort; for further information, see [122-124].

Figure 12. Unit operations of a fermentation process
[Full View]

In the past, biotechnological process development may have looked somewhat like an art because adequate process control was lacking. This chapter should show that, based on the present state of the art, a production process can be highly controlled. To achieve this level of control in fermentation, the organism must be genetically adapted, and the process protocol must match the physiological possibilities of the organism and the limitations of the apparatus.

3.1.1. Organism and Enzyme Synthesis

A variety of different microorganisms are used for the industrial production of enzymes. They cover the taxonomic gamut from eukaryotic systems such as yeasts and fungi to prokaryotic systems from both the gram-negative and gram-positive families. When biopharmaceutical enzymes are considered as well, mammalian and insect cell lines also come into play. For most of the history of enzyme applications, production occurred in the strain known to make the enzyme of interest. This explains why so many different types of microorganisms have been employed to make enzymes. Alkaline protease is naturally secreted by *Bacillus licheniformis* to break down proteinaceous substrates and resulted in one of the first commercially produced enzymes, subtilisin Carlsberg, for use in detergents. Strains were selected that produced higher levels of protease, and an industry was born. A similar story was followed for α-amylase production. Again, *Bacillus licheniformis* naturally secreted a highly thermostable α-amylase capable of breaking down starch to more easily digestible oligosaccharides. Strains of *Bacillus* have been one of the

workhorses of enzyme production for decades, based mainly upon their ability to overproduce subtilisin and α-amylase [125].

Amylase from *Bacillus* has historically been used to liquefy starch. However, to break it down completely to single units of glucose, a second enzyme, namely, glucoamylase, is required. The most widely used enzyme for glucose production from starch is the glucoamylase from strains of the fungal genus *Aspergillus* [126]. Overproducing strains have been isolated over the years that have led to high production of glucoamylase.

An acid cellulase enzyme complex is found in the fungus *Trichoderma* [127]. This enzyme mixture was thought to be capable of breaking down cellulosic substrates to glucose, similar to the starch-degrading enzymes. This particular application was not initially commercialized. Instead, it has found applications in the treatment of textiles. New programs to improve the enzyme complex and its expression are resurrecting its potential use as an additive for the breakdown of cellulose. As with the other systems above, more productive strains have been isolated.

A final example is the production of glucose/xylose isomerase. Glucose isomerase catalyzes the rearrangement of glucose to fructose, yielding a product with a sweeter taste. The enzyme discovered to be capable of industrial conversion originated from a species of *Steptomyces*. As with the others, the native host strain has been used for production of glucose isomerase.

All of the strain types described in the examples above are capable of differentiation. For example, *Bacillus* thrives in nature due to its ability to survive various insults by forming a non growing, yet viable, spore. The spore remains dormant until it reaches an environment where it can germinate and divide. Regulation of protease production is associated with this differentiation. This highly complex behavior has been difficult to model for aiding process development. The same can be said of the fungal species *Aspergillus* and *Trichoderma*. Their differentiation makes process development and modeling difficult. Although *Streptomyces* does not truly sporulate, it differentiates by forming filaments as opposed to isolated individual cells. This property also has an effect on product formation and physical properties of the fermentation broth.

An organism can be viewed as a metabolic system converting substrates into cell mass and byproducts. Enzymes function in this system as catalysts for the different reactions. Each cell is equipped with mechanisms that regulate the synthesis and activity of the enzymes to enable the cell to respond adequately to environmental changes. Therefore, in its elementary form, an organism can be described as a set of metabolic components with a mechanism for enzyme synthesis and a regulatory apparatus. The kinetics of the process are determined by structural components of the organism and by various physical and chemical factors, as shown in Figure 13. The key role that enzymes play in biological processes has led to an extensive study of both the mechanism and the regulation of their synthesis [128], [129], and some of the results are related to the problem of process development.

Figure 13. Scheme of the metabolic process
[Full View]

The basic mechanisms of enzyme synthesis, including transcription, translation, and posttranslational processing, seem to be highly conserved [124]. However, several differences exist between various classes of organisms, as well as some fundamental differences between prokaryotic and eukaryotic organisms. The enzymes themselves differ enormously in molecular mass, number of polypeptide chains, isoelectric point, and degree of glycosylation. In addition, a variety of enzyme-producing species exist [131]. Although all the differences may influence the characteristics of synthetic patterns, the basic mechanisms underlying enzyme synthesis are similar enough to allow a general treatment of the microbiological production process. However, the differences in production kinetics among various species are large enough to make individual optimization programs necessary.

Different organisms may also differ in their suitability for fermentation; such process characteristics as viscosity or recoverability, legal clearance of the organism, and knowledge available on the selected organism, must be considered.

Because of the action of the regulatory mechanism, enzyme synthesis rates range from no synthesis to maximum synthesis allowed by the synthetic apparatus, as in a normal control loop. The complexity of mechanisms ranges from relatively simple and well-understood induction and repression systems, to very complex global regulatory networks [132].

Process development must deal with the complexity of the enzyme synthesis system either by changing the structural characteristics, including structural elements of the regulatory systems (see Section Strain Improvement), or by selecting optimal environmental conditions (see Section Physiological Optimization).

3.1.2. Strain Improvement

Most of the strains used for enzyme production have been improved through classical selection. Mutagenesis by chemical agents or UV radiation has been used to more quickly find useful variants. Many cells must be subjected to a mutation or recombination procedure and then tested for the desired combination of characteristics by selection. The success of strain improvement programs often depends on development of an effective selection method for finding one mutant among 10 000–100 000 cells. Methods range from plate selection to the continuous culture technique [137], [138].

Mutation changes the protein structure and most probably results in a deterioration of function. Changes in structural components by mutation are therefore rarely improvements unless the specific loss of function is required for production purposes, e.g., when a loss of regulatory function results in enhanced enzyme production.

Mutation and selection are directed primarily toward higher overall productivity rather than mutation of a specific function, but a loss of regulatory function is highly probable. However, some studies describe screening for a mutation in a specific function [135].

Based on the complex interdependency of pathways and the competition for substrates in the organism, random mutation may also affect the rate of enzyme synthesis. However, only minor improvements should be expected, although a series of mutations can still result in an interesting degree of improvement. In vivo recombination techniques have been used to complement mutation techniques by bringing together mutations in different cell lines and cleaning strains of undesired deleterious mutations [122]. Strain improvement has been revolutionized by the advent of genetic engineering. The ability to specifically improve strains by the manipulation of the host genome or the addition of extra-chromosomal DNA elements has greatly increased the speed of strain improvement. In the early stages, most work was performed in strains for which methods to manipulate DNA were established. Attempts were made to express many different enzymes in *Escherichia coli*. However, *E. coli* typically does not excrete such proteins and instead deposits them in an insoluble form (called inclusion bodies) in the cytoplasm of the cell. It proved more effective to develop DNA manipulation techniques in the native host strain of the different enzymes. Today, nearly all production strains used commercially have been genetically engineered. Strains have been improved through extra copies of the gene of interest, removal of inhibitory regulation, and enhancement of positive regulation.

If the absence of regulation is assumed, considerable improvement can be realized by increasing the turnover rate of the limiting step in synthesis. Techniques of genetic engineering can be used to increase the rate of mRNA synthesis by constructing plasmids with the desired gene (gene multiplication). The number of plasmids per cell can be very high. The rate of mRNA synthesis should be related linearly to the number of gene copies, but the rate of enzyme synthesis may be limited again by the next step in the process. These techniques also allow replacement of the promoter by a more effective one [139]. The same methods allow replacement of the leader sequence of a gene, resulting in the excretion of a formerly intracellular enzyme [140].

Genetic engineering also uses microorganisms to produce enzymes of higher organisms by placement of the corresponding gene into the microorganism. The presence of introns may then prevent proper expression of the gene, but techniques have been developed to overcome this difficulty [136]. Chymosin (E.C. 3.4.23.4) [

9001-98-3], calf rennet, has been cloned by several groups either in prokaryotes or in yeast, one of the first cloned mammalian enzyme to be produced industrially by microorganisms [141].

Novel methods to improve strain performance are under development (ca. 2002). These include gene shuffling and directed evolution. Most of the literature regarding these techniques has focused on the improvement of specific enzyme properties (see Section Protein Engineering). However, directed evolution is now being applied to the overproduction of given enzymes as well. By mutagenizing a plasmid harboring a gene for subtilisin, enzyme production was increased five fold [142]. It was shown that the structural gene was unchanged and that the effect was most likely due to an improved promoter or higher plasmid copy number leading to higher rates of transcription.

3.1.3. Physiological Optimization

Figure 13 shows that not only the structural characteristics of the system, but also the input parameters, determine its metabolic activity. Once a suitable organism has been found, either genetically improved or not, the next task of process development is to define optimal input parameters.

The rate of enzyme synthesis r_e is defined by:

$$r_e = q_e \cdot c_x$$

where r_e is the enzyme synthesis rate in units per liter per hour (for definition of unit, see Section Definition of Units), q_e the specific enzyme synthesis rate in units per gram of biomass per hour, and c_x the biomass concentration in grams per liter.

In kinetic terms, optimization of the enzyme synthesis rate means finding the highest specific synthesis rate for a given amount of biomass. Because enzyme synthesis depends so much on primary metabolism, the complete cellular machinery must function at all times. Therefore, conditions favoring enzyme synthesis also favor growth, as suggested in Figure 13. The search for optimal conditions for enzyme synthesis can then be reduced to a search for (1) the conditions influencing growth rate and (2) the relation between specific enzyme synthesis rate and growth rate.

Growth can be expressed by a specific growth rate μ as the amount of biomass synthesized per unit biomass and unit time:

$$\mu = \frac{1}{c_x} \cdot \frac{dc_x}{dt}$$

where c_x is the biomass concentration in grams per liter and t the time in hours.

Specific enzyme synthesis rate and specific growth rate express the metabolic activities of the cell. These are abbreviated as synthesis rate q_e and growth rate μ. MONOD [143] formulated the relationship between growth rate and substrate concentration as:

$$\mu = \mu_{max} \cdot \frac{c_s}{K_s + c_s}$$

where μ_{max} is the maximum obtainable growth rate per hour; K_s is the saturation, and c_s the concentration of substrate, both expressed as moles per liter.

According to this relation actual growth rates at low substrate concentration are lower than the maximum possible value determined by the structural properties of the organism. When $c_s \gg K_s$, the growth rate reaches its maximum value. If all substrates are present in excess ($c_{s_i} \gg K_{s_i}$ for any i), the growth rate is limited by internal structure. The parameters μ_{max} and K_s are dependent on pH, temperature, osmotic pressure, and such factors as medium type (minimal vs. nutrient medium). When all substrates are present in

excess except one ($\mu < \mu_{max}$), that substrate is called the limiting factor; in this case, an external growth limitation exists. Nutrient-limited growth is considered the natural state for microorganisms [144].

The kinetics of enzyme synthesis cannot be expressed in one equation for all enzymes. Instead, a number of patterns of synthesis rate q_e versus growth rate μ are shown in Figure 14. The curves are somewhat idealized, but many examples can be found in the literature [145-148].

Figure 14. Types of relationship between specific synthesis rate q_e and specific growth rate μ

A): Growth-coupled synthesis [147]; B): Saturated synthesis [148]; C): Saturated synthesis with catabolic repression [151]; D): Repressed synthesis [154]
[Full View]

The importance of these physiological considerations is that a limiting factor can be used to control growth rate and thereby synthesis rate. If the q_e versus μ relationship is known, the value of μ that results in a maximum q_e corresponds to the optimal physiological condition for synthesis.

Complete physiological characterization includes knowledge of the relationship of q_e to μ, the yield on different substrates, the effect of the limiting factor, the physicochemical conditions, and the possible role of regulatory agents. Because these factors are interdependent, establishment of the complete physiological characteristics of an organism is a very extensive task. In industrial practice, experience, general knowledge, and use of well-known organisms or techniques are generally employed to find shortcuts.

The previous discussion emphasizes the importance of the limiting factor for control of growth and product synthesis. Control of growth is possible if the substrate concentration c_s is in the range of the saturation concentration K_s. The K_s values for most substrates (± 0.1 mmol/L) are rather low compared to the consumption rate (± 10 mmol L^{-1} h^{-1} for glucose), i.e., the response time constant (less than a minute) is low. Continuous feed is therefore necessary to control growth rate by limiting substrate concentration, as applied in fed-batch and continuous cultures. In batch cultures, all substrates are present at the start of fermentation, and the growth rate is maximal until the substrate is nearly consumed. Therefore, direct control of growth is not possible in a batch culture.

One of the applications of metabolic-pathway engineering to fermentation production technologies is the ever-expanding “toolbox” to enable mining of biodiversity, maximize productivity, enhance carbon efficiency, improve product purity, expand product lines, and broaden markets. Functional genomics, proteomics, metabolomics, fluxomics, physiomics, and cellomics applications holistically delineate metabolic pathways and environment within the host [149]. Functionomics-based optimization includes four key elements: (1) completion and optimization of the primary metabolic pathway to the targeted product, including removal of rate-limiting, transcriptional, and allosteric regulation; (2) genetic blockage of competing pathways; (3) enhanced carbon commitment to the primary metabolic pathway from central metabolism; and (4) modification of secondary metabolic pathways as necessary to enhance energy metabolism and availability of required enzymatic cofactors. Recently, strain-specific stoichiometry (metabolic genotype) has been woven into flux balance models to determine optimal flux distributions (metabolic phenotype) by using linear programming. A combination of such approaches may prove to be valuable for design and optimization of bioprocesses [150].

3.1.4. The Fermentor and its Limitations

Fermentation process design is interdisciplinary and uses concepts and methodologies of both chemical engineering and microbial physiology to accomplish scale-up. In practice, scale-up effects are more pronounced for aerobic, i.e., aerated and agitated environment, than for anaerobic fermentations. Therefore, as a rule of thumb, in an aerobic fermentor, the constant oxygen transfer rate and concentration of dissolved oxygen are generally maintained in the scale-up. While thermodynamic and kinetic phenomena are

independent of scale, momentum, mass and heat transfer are functions of scale. Mixing, aeration, and cooling are well controlled and uniform at 10 L scale, but not all transport parameters can be maintained in this way at large scale. Further scale-up complications arise from cell response to distributed values of dissolved oxygen, temperature, pH, and nutrients.

The development of entirely new processes or the improvement of existing processes requires the evaluation of a wide range of strains and cultivation conditions in a short period of time. Shake-flask fermentation studies have a cost advantage but lack process control options (pH, nutrient addition, aeration). This often leads to use of laboratory-scale (ca. 10 L) agitated, aerated fermentors with adequate instrumentation and control. Most fermentation processes can be translated to production scale by use of laboratory-scale fermentors. However, pilot-scale fermentors are often necessary for downstream process scale-up.

For enzyme production, economy of scale leads to the use of fermentors with a volume of 20–200 m^3. The higher energy yield from aerobic metabolism results in the use of aerobic processes which require continuous transfer of poorly soluble oxygen into the culture broth. The concomitant problems of mass and heat transfer are usually neglected in small fermentors and at low cell densities. However, in industrial microbiology, with the above-mentioned fermentor volumes and the economic necessity of using the highest possible cell densities, transport processes must be considered. Such processes can limit metabolic rates; for example, the oxygen supply may become limiting and the microorganism may respond by changes in its physiological pattern. Under these conditions, the desired control of microbial metabolism may be lost. In controlled operation of an industrial process, metabolic rates must be limited to a level just below the transport capacity of the fermentor. Therefore, the highest possible productivity in a fermentor is obtained at maximal transport capacity. This is reflected in low concentrations of dissolved oxygen during fermentation, as shown in Figure 15.

Figure 15. Schematic representation of a fermentation

This illustrates the production of amylase by *B. licheniformis*. After an inital exponential growth period, the process is controlled by an increasing feed rate which results in the oxygen uptake rate and biomass profile shown. The final result is an almost constant rate of enzyme synthesis during fermentation

Variables (expressed as percent of maximum value during fermentation):

c_x, biomass concentration; c_e, enzyme activity; *DO*, dissolved oxygen; *OUR*, oxygen uptake rate; Φ_s, carbon feed rate
[Full View]

Maximizing the transport processes is chiefly a problem of fermentor design and is generally treated in handbooks on bioengineering [121], [123], [151], [152], [153]. In the common stirred-tank reactor, agitation and injection of compressed air are used to mix the contents of the reactor and to transfer gases. The oxygen transport rate *n*, for example, can be expressed as:

$$n = k_1 a[c_0(\mathrm{g}) - c_0(1)]$$

where $k_1\ a$ is the transfer coefficient per hour; c_0 (g) is the oxygen concentration in the liquid phase in equilibrium with the gas phase, and c_0 (l) the actual oxygen concentration in the medium, both expressed in millimoles per liter.

The transfer coefficient $k_1\ a$ shows that the main resistance to oxygen transport is the gas – liquid interface, where k_1 is the resistance coefficient in meters per hour, and *a* the total gas – liquid interface area in square meters per cubic meter. The transfer capacity of a fermentor can be expressed as the $k_1\ a$ value. The $k_1\ a$ value is determined primarily by the power input of the agitator and the air jet system [154]. Bioengineering therefore aims at the design of a fermentor with the highest $k_1\ a$ value at the lowest power input.

The $k_1 a$ value is also influenced by factors such as viscosity, ionic strength, and presence of surfactants. The dependence of $k_1 a$ on viscosity explains the preference for using pellet growth to cultivate mycelium-forming microorganisms [155].

The complex relationships of factors determining transport processes make the scale-up of biotechnological processes a very difficult task [122].

3.1.5. Process Design

Process design entails the development of an optimum outcome for process performance. This typically begins at the fermentation stage, but must also take into account downstream operations such as cell harvesting, product isolation, enzyme purification, and final product formulation. The way in which these unit operations interact can have a profound effect upon optimum process performance.

The fermentation stage begins with culture storage. Cell lines can be stored for future use in a number of ways. These include cultures frozen in liquid media with an appropriate cryoprotectant, on or within solid media such as agar, as freeze-dried suspensions, and as spore suspensions. The process of reviving the stored culture is an oft-neglected phase of the fermentation process. Development time typically focuses on operation of the production fermentor, and the seed stages are run simply to grow the cells as quickly as possible. A typical seed train is shown in Figure 16. However, the physiological state in which the cells are cultivated during seed propagation can have a profound effect upon fermentor performance. This is especially true for microorganisms that can differentiate, either through filamentation or sporulation. For genetically engineered strains, maintaining strain stability is of utmost concern.

Figure 16. Typical fermentation train
[Full View]

The desired outcome of the fermentation process is often to maximize the enzyme synthesis rate, or volumetric productivity. This rate is the product of the specific enzyme production rate and the cell concentration (see Section Physiological Optimization). Both of these factors can be influenced by process design. If the specific production rate is a strong function of growth rate, i.e., growth-associated production, maintenance of high growth rate will be of high priority. In such cases, continuous-culture techniques are quite suitable. The constant removal of cell mass allows for sustained high growth rate and specific productivity. The high metabolic rate associated with high growth rate can limit the achievable cell mass concentration. Oxygen- and heat-transfer limitations of the fermentation equipment are usually the limiting factors.

Some enzymes are produced more as a secondary metabolite, and specific productivity may then be an inverse function of growth rate, i.e., non-growth-associated production. Here a recycling reactor may be most suitable. A recycling reactor is similar to the continuous culture, but a device is added to return a significant fraction of the cells to the reactor. Low growth rates with high cell concentration can often be achieved in such systems.

In many cases, however, the relationship between growth rate and specific productivity can be quite complex, so that neither the continuous-culture nor the recycling fermentor is a good choice. This is where fed-batch processes are most prevalent. Starting with a relatively low cell mass concentration, growth rate can be controlled throughout the course of the fermentation through feeding of a growth-limiting substrate.

The discussion above is focused on optimization of the fermentation process. Yet the goal of most processes is to produce a final formulated enzyme product and will likely include many post-fermentation unit operations. For the entire process, maximum production rate could still be the most important factor. However, lowest unit production cost could also be an important driving force. Optimization of each individual unit operation will not always lead to the optimal overall process performance, especially when there are strong interactions between unit operations [156]. Understanding of these interactions is crucial to overall process optimization. For instance, product concentration or purity in the fermentation broth can

significantly impact downstream purification unit operation. If the fermentation is optimized for productivity, without taking into account its effect on the purification step, the overall process productivity can be negatively affected. The use of antifoaming agents in the fermentation process is another example of such a trade-off. By reducing foaming in the fermentation, a higher working volume can be used to optimize the fermentation unit operations. However, many antifoaming agents negatively impact ultrafiltration membranes and reduce the capacity of this recovery unit operation [157]. Knowledge of how the fermentation process will affect other downstream unit operations is also of great importance.

3.1.6. Modeling and Optimization

Many enzyme production processes are carried out on a large scale (> 100 000 L). Small increases in performance can have a significant impact on economic viability. Therefore, process optimization is of great importance for enzyme production by fermentation. Process modeling can give a structured approach to the optimization problem so that optimal conditions can quickly be reached.

Relationships between controllable parameters and desired outputs are a prerequisite for successful process modeling. Balance equations combined with kinetic expressions have been the most widely used tools for such modeling. Monod-type kinetic expressions (see Section Physiological Optimization) are a typical starting point. This type of modeling has been successfully applied to the improvement of enzyme production processes. Kinetic expressions of cell growth, substrate utilization, and product formation are formulated. Whenever possible, independent experimental procedures are utilized to determine model parameters. Fermentation experiments are then performed to fit any remaining parameters. Mathematical simulations are then run to predict the performance of the system based upon known adjustable parameters, such as substrate feed rate. Optimization can be carried out “in silico” for any given objective function (e.g., maximum product concentration or maximum production rate). In fact, combinations of different parameters can simultaneously be optimized to meet conflicting constraints [158]. Experimental fermentations can then be used to calibrate and validate the model. Adjustments to the model architecture can be made to improve the predictive capability of the model. Continual iteration between model modification and experimental results is a trademark of such kinetic modeling.

The drawback of such models is the prerequisite for relationships between the controllable parameters and the desired outputs. One way around this impediment is the use of artifical neural networks (ANNs) [159], [160], [162]. These adaptive computer programs have the ability to learn and can be used for predictions if properly trained. Advantageously, many enzyme production processes have a large repository of past data that can be used to build and train such models. The ANN consists of a set of input and output variables determined by the process being investigated. A set of nodes is then established between the inputs and outputs, each with a different weighting factor. The optimal number of nodes is typically found through trial and error. The weighting factors are continually updated by “training” on actual process data. New inputs and outputs can be added to help improve the predictive power of the model. Such procedures have been used for enzymes and other microbially derived products.

ANNs can be extended by combining them with a more structured model to create hybrid models [161]. Input variables can be placed into an ANN and the output variables can then be used as the input to a set of balance equations. Such models have shorter training times as they combine the black-box approach of the ANN with known relationships between controllable parameters and desired outputs.

3.1.7. Instrumentation and Control

Like any chemical reactor, fermentors are controlled by monitoring and estimating several critical parameters such as pressure, temperature, pH, dissolved oxygen, redox potential, foam level, heat flux via coolant supply, respiration (carbon dioxide, oxygen) rate, mass- and heat-transfer coefficients (Figure 17). Mass spectrometry is commonly used for analyzing the off-gas composition for calculating oxygen uptake rate, carbon dioxide evolution rate, oxygen transfer coefficient k_1a, respiration coefficient, and carbon balance.

Figure 17. Bioreactor monitoring and control
[Full View]

Typically, fermentation is optimized by careful design of batch and feeding media, in order to regulate cell growth and maximize production. When an optimal trajectory of the feed rate has been found and desired values for physicochemical variables have been established, the process is ready for production scale. Elementary physical variables, pH, and feed rate are maintained by proper control. If process development is of reasonable quality, the resulting output will be somewhere in the expected range. In practice, however, deviations between actual and expected results may arise for several reasons: (1) the model and the experimental knowledge are never complete; (2) errors of measurement and set point always exist, along with deviations in the variables regulated; (3) raw materials may vary in composition; and (4) transport conditions can cause deviations in response.

If deviations from the expected results are minimal, the process can be operated with a minimum level of instrumentation and control. If the deviations cannot be ignored, output variables may be measured to correct input variables; for example, the carbon dioxide production rate can be used for feedback regulation of the feed rate. More advanced control can be realized when a model of the process is used to relate different input and output variables. The measured input and output variables of the process can be compared with the model, and some type of regulatory action can be derived from this comparison [168].

Fermentation processes are complicated, and in principle, control of the process can be improved by measuring as many variables as possible and using them for computer-based process control and optimization. A general limitation of such control systems is lack of adequate (cheap and sterilizable) sensors for measuring the chemical and biological variables [169]. Another problem is the lack of persons to develop the software and operate such systems [170]. Optimistically, reliable measurements and models will lead to on-line estimation and control of variables not measured, using balances for mass and elements, and phenomenological relations for mass transfer and acid-base equilibria in combination with the electroneutrality condition [171].

3.2. Isolation and Purification [172-187]

The degree of purity of commercial enzymes ranges from raw enzymes to highly purified forms and depends on the application. Raw materials for the isolation of enzymes are animal organs, plant material, and microorganisms.

Enzymes are universally present in living organisms; each cell synthesizes a large number of different enzymes to maintain its metabolic reactions. The choice of procedures for enzyme purification depends on their location. Isolation of intracellular enzymes often involves the separation of complex biological mixtures. On the other hand, extracellular enzymes are generally released into the medium with only a few other components. Enzymes are very complex proteins, and their high degree of specificity as catalysts is manifest only in their native state. The native conformation is attained under specific conditions of pH, temperature, and ionic strength. Hence, only mild and specific methods can be used for enzyme isolation. Figure 14 shows the sequence of steps involved in the recovery of enzymes.

3.2.1. Preparation of Biological Starting Materials

Animal Organs. Animal organs must be transported and stored at low temperature to retain enzymatic activity. The organs should be freed of fat and connective tissue before freezing. Frozen organs can be minced with machines generally used in the meat industry, and the enzymes can be extracted with a buffer solution. Besides mechanical grinding, enzymatic digestion can also be employed [188]. Fat attached to the organs interferes with subsequent purification steps and can be removed with organic solvents. However, enzymatic activity might be influenced negatively by this procedure.

Plant Material. Plant material can be ground with various crushers or grinders, and the desired enzymes can be extracted with buffer solutions. The cells can also be disrupted by previous treatment with lytic enzymes.

Microorganisms are a significant source of enzymes. New techniques, summarized under genetic and protein engineering, have much to offer the enzyme industry. A gene can be transferred into a microorganism to make that organism produce a protein it did not make naturally. Alternatively, modification of the genome of a microorganism can change the properties of proteins so that they may be isolated and purified more easily. Such modifications might, for example, cause the release of intracellular enzymes into the medium; change the net charge and, therefore, the chromatographic properties of proteins; or lead to the formation of fused proteins [189].

Most enzymes used commercially are *extracellular enzymes*, and the first step in their isolation is separation of the cells from the solution. For *intracellular enzymes*, which are being isolated today in increasing amounts, the first step involves grinding to rupture the cells. A number of methods for the disruption of cells (Table 2) are known, corresponding to the different types of cells and the problems involved in isolating intracellular enzymes. However, only a few of these methods are used on an industrial scale.

Table 2. Methods for disruption of cells

Mechanical methods	Nonmechanical methods	
High pressure (Manton – Gaulin, French-press)	Drying (freeze-drying, organic solvents)	
Grinding (ball mill)	Lysis	
Ultrasound	physical:	freezing, osmotic shock
	chemical:	detergents, antibiotics
	enzymatic:	enzymes (e.g., lysozyme), antibiotics

3.2.1.1. Cell Disruption by Mechanical Methods

High-pressure homogenization is the most common method of cell disruption. The cell suspension is pressed through a valve and hits an impact ring (e.g., Manton – Gaulin homogenizer). The cells are ruptured by shearing forces and simultaneous decompression. Depending on the type of machine, its capacity ranges from 50 to 5000 L/h. The rigid cell walls of small bacteria are only partially ruptured at the pressures up to 55 MPa (550 bar) achieved by this method. Higher pressures, however, would result in further heat exposure (2.2 °C per 10 MPa). Hence, the increased enzyme yield resulting from improved cell disruption could be counteracted by partial inactivation caused by heating and higher shearing forces. Therefore, efficient cooling must be provided.

The *wet grinding* of cells in a high-speed bead mill is another effective method of cell disruption [190-193]. Glass balls with a diameter of 0.2 – 1 mm are used to break the cells. The efficiency of this method depends on the geometry of the stirrer system. A symmetrical arrangement of circular disks gives better results than the normal asymmetrical arrangement [194]. Given optimal parameters such as stirring rate, number and size of glass beads, flow rate, cell concentration, and temperature, a protein release of up to 90 % can be achieved in a single passage [190].

3.2.1.2. Cell Disruption by Nonmechanical Methods

Cells may frequently be disrupted by *chemical*, *thermal*, or *enzymatic lysis*. The drying of microorganisms and the preparation of acetone powders are standard procedures in which the structure of the cell wall is altered to permit subsequent extraction of the cell contents. Methods based on enzymes or autolysis have been described in the literature [195-198]. Ultrasound is generally used in the laboratory. In this procedure, cells are disrupted by shearing forces and cavitation. An optimal temperature must be maintained by cooling

the cell suspension because heat is generated in the process. Additional problems may arise from generation of free radicals.

3.2.2. Separation of Solid Matter

After cell disruption, the next step is separation of extracellular or intracellular enzymes from cells or cellular fragments, respectively. This operation is rather difficult because of the small size of bacterial cells and the slight difference between the density of the cells and that of the fermentation medium. *Continuous filtration* is used in industry. Large cells, e.g., yeast cells, can be removed by *decantation.* Today, efficient *centrifuges* have been developed to separate cells and cellular fragments in a continuous process. Residual plant and organ matter can be separated with simpler centrifuges or filters.

3.2.2.1. Filtration

The filtration rate is a function of filter area, pressure, viscosity, and resistance offered by the filter cake and medium (→ Filtration). For a clean liquid, all these terms are constant which results in a constant flow rate for a constant pressure drop. The cumulative filtrate volume increases linearly with time. During the filtration of suspensions, the increasing thickness of the formed filter cake and the concomitant resistance gradually decrease the flow rate. Additional difficulties may arise because of the compressibility of biological material. In this case, the resistance offered by the filter cake and, hence, the rate of filtration depend on the pressure applied. If the pressure applied exceeds a certain limit, the cake may collapse and total blockage of the filter can result.

Pressure Filters. A *filter press* (plate filter, chamber filter) is used to filtrate small volumes or to remove precipitates formed during purification. The capacity to retain solid matter is limited, and the method is rather work-intensive. However, these filters are highly suitable for the fine filtration of enzyme solutions.

Vacuum Filters. Vacuum filtration is generally the method of choice because biological materials are easily compressible. A *rotary vacuum filter* (Figure 15) is used in the continuous filtration of large volumes. The suspension is usually mixed with a filter aid, e.g., kieselguhr, before being applied to the filter. The filter drum is coated with a thin layer of filter aid (precoat). The drum is divided into different sections so that the filter cake can also be washed and dried on the filter. The filter cake is subsequently removed by using a series of endless strings or by scraper discharge (knife). The removal of a thin layer of precoat each time exposes a fresh filtering area. This system is useful for preventing an increase in resistance with the accumulation of filter cake during the course of filtration.

Cross-flow filtration [198], [200]. In conventional methods, the suspension flows perpendicular to the filtering material (Fig. 18 A). In cross-flow filtration, the input stream flows parallel to the filter area (Fig. 18 B), thus preventing the accumulation of filter cake and an increased resistance to filtration. To maintain a sufficiently high filtration rate, this method must consume a relatively large amount of energy, in the form of high flux rates over the membranes. With the membranes now available, permeate rates of 30 – 50 $Lm^{-2}\ h^{-1}$ can be attained. Indeed, in many cases the use of a separator (see Section Centrifugation) is more economical [199]. The future of this method depends on the development of suitable membranes, but cross-flow filtration can be conveniently used in recombinant DNA techniques to separate organisms in a closed system.

Figure 18. Sequence of steps in the isolation of enzymes [Full View]

3.2.2.2. Centrifugation

The sedimentation rate of a bacterial cell with a diameter of 0.5 µm is less than 1 mm/h. An economical separation can be achieved only by sedimentation in a centrifugal field (→ Centrifuges, Sedimenting). The

range of applications of centrifuges depends on the particle size and the solids content (Table 3).

Table 3. Utilization of different centrifuges

Type of centrifuge	Solids content, %	Particle size, µm
Multichamber separator	0 – 5	0.5 – 500
Desludging disk separator	3 – 10	0.5 – 500
Nozzle separator	5 – 25	0.5 – 500
Decanter	5 – 40	5 – 50 000
Sieve centrifuge	5 – 60	5 – 10 000
Pusher centrifuge	20 – 75	100 – 50 000

The Σ value of a centrifuge is a good criterion for the comparison of centrifuges:

$$\Sigma = F \cdot Z$$

where $F = V/S$, with V the total volume of liquid in the centrifuge and S the thickness of the liquid layer in the centrifuge; i.e., F has the units of an area. $Z = r \cdot \omega^2/g$, where r is the radius of the centrifuge drum, ω the angular rotation speed, and g the gravitational constant.

Both sieve centrifuges and solid-wall centrifuges are available. Typical solid-wall centrifuges are shown in Figure 19.

Figure 19. Rotary vacuum filter
[Full View]

Decanters (scroll-type centrifuges) work with low centrifugal forces and are used in the separation of large cells or protein precipitates. Solid matter is discharged continuously by a screw conveyer moving at a differential rotational speed.

Tubular bowl centrifuges are built for very high centrifugal forces and can be used to sediment very small particles. However, these centrifuges cannot be operated in a continuous process. Moreover, solid matter must be removed by hand after the centrifuge has come to a stop. A further disadvantage is the appearance of aerosols.

Separators (disk stack centrifuges) can be used in the continuous removal of solid matter from suspensions. Solids are discharged by a hydraulically operated discharge port (intermittent discharge) or by an arrangement of nozzles (continuous discharge). Bacteria and cellular fragments can be separated by a combination of high centrifugal forces, up to 15 000 × gravity, presently attainable, and short sedimentation distances. Disk stack centrifuges that can be sterilized with steam are used for recombinant DNA techniques in a closed system [201], [202].

3.2.2.3. Extraction

An elegant method used to isolate intracellular enzymes is liquid – liquid extraction in an aqueous two-phase system [203-207]. This method is based on the incomplete mixing of different polymers, e.g., dextran [9004-54-0] and poly(ethylene glycol) [25322-68-3], or a polymer and a salt in an aqueous solution [208]. The first extraction step separates cellular fragments. Subsequent purification can be accomplished by extraction or, if high purity is required, by other methods. The extractability can be improved by using affinity ligands [209], [210] or modified chromatography gels, e.g., phenyl-Sepharose [211].

3.2.2.4. Flocculation and Flotation

Flocculation. Separation of bacterial cells or cell debris by filtration or centrifugation can involve considerable difficulties due to their small size and physical properties. The compressible nature of the cells is the primary limiting factor for using filtration as a separation step to remove them. The low permeability of a typical cell cake results in a filtration rate that is often too slow to be practical. In cell removal by centrifugation, the small size and low density difference between the cells or cell debris and the medium results in a low sedimentation rate. Flocculation of cell suspensions has been reported to aid cell separation by both filtration and centrifugation [212-218].

Flocculation is the process whereby destabilized particles are induced to come together, make contact, and subsequently form larger aggregates. Flocculating agents are additives capable of increasing the degree of flocculation of a suspension (→ Flocculants) . They can be organic or inorganic, and natural or synthetic. A comprehensive review of various categories of flocculating agents can be found in [219], [220]

Synthetic organic flocculating agents are by far the most commonly used agents for cell flocculation in industrial processes. They are typically water-soluble, charged polymeric substances with average molecular weight ranging from about 10^3 to greater than 5×10^6 and are generally referred to as polyelectrolytes. The positively and negatively charged polymers are referred to as cationic and anionic polyelectrolytes, respectively. Polyelectrolytes containing both positive and negative charges are termed polyampholytes.

Flocculation of cells by polyelectrolytes is a two-step process. The first step is the neutralization of the surface charge on the suspended cells or cell debris. The second step involves the linkage of these particles to form large aggregates. The various mechanisms and theories of flocculation have been summarized [219-222].

Flocculant selection for a specific cell separation process is a challenge as many factors can impact flocculation. These factors can have their origin in the broth (cell surface charge and size, ionic strength, pH, cell concentration, and the presence of other charged matter), the polymer (molecular weight, charge and charge density, structure, type), and engineering parameters (mixing and mode and order of addition). The final criteria for flocculant selection should take into consideration all aspects of the flocculation process. These include the cost of the added flocculant, subsequent separation performance, process robustness, and yield. In some cases, flocculation can also provide purification by selectively removing unwanted proteins, nucleic acids, lipids and endotoxin from the cell broth [223-226].

Flotation. If no stable agglomerates are formed, cells can be separated by flotation. Here, cells are adsorbed onto gas bubbles, rise to the top, and accumulate in a froth. An example is the separation of single cell protein [227].

3.2.3. Concentration

The enzyme concentration in starting material is often very low. The volume of material to be processed is generally very large, and substantial amounts of waste material must be removed. Thus, if economic purification is to be achieved, the volume of starting material must be decreased by concentration. Only mild concentration procedures that do not inactivate enzymes can be employed. These include *thermal methods, precipitation,* and to an increasing extent, *membrane filtration.*

3.2.3.1. Thermal Methods

Only brief heat treatment can be used for concentration because enzymes are thermolabile. Evaporators with rotating components that achieve a thin liquid film (thin-layer evaporator, centrifugal thin-layer evaporator) or circulation evaporators (long-tube evaporator) can be employed.

3.2.3.2. Precipitation

Enzymes are very complex protein molecules possessing both ionizable and hydrophobic groups which interact with the solvent. Indeed, proteins can be made to agglomerate and, finally, precipitate by changing their environment. Precipitation is actually a simple procedure for concentrating enzymes [228].

Precipitation with Salts. High salt concentrations act on the water molecules surrounding the protein and change the electrostatic forces responsible for solubility. Ammonium sulfate [7783-20-2] is commonly used for precipitation; hence, it is an effective agent for concentrating enzymes. Enzymes can also be fractionated, to a limited extent, by using different concentrations of ammonium sulfate. The corrosion of stainless steel and cement by ammonium sulfate is a disadvantage, which causes additional problems in wastewater treatment. Sodium sulfate [7757-82-6] is more efficient from this point of view, but it is less soluble and must be used at temperatures of 35 – 40 °C. The optimal concentration of salt required for precipitation must be determined experimentally, and generally ranges from 20 to 80 % saturation.

Precipitation with Organic Solvents. Organic solvents influence the solubility of enzymes by reducing the dielectric constant of the medium. The solvation effect of water molecules surrounding the enzyme is changed; the interaction of protein molecules is increased; and therefore, agglomeration and precipitation occur. Commonly used solvents are ethanol [64-17-5] and acetone [67-64-1]. Satisfactory results are obtained only if the concentration of solvent and the temperature are carefully controlled because enzymes can be inactivated easily by organic solvents.

Precipitation with Polymers. The polymers generally used are polyethylenimines and poly(ethylene glycols) of different molecular masses. The mechanism of this precipitation is similar to that of organic solvents and results from a change in the solvation effect of the water molecules surrounding the enzyme. Most enzymes precipitate at polymer concentrations ranging from 15 to 20 %.

Precipitation at the Isoelectric Point. Proteins are ampholytes and carry both acidic and basic groups. The solubility of proteins is markedly influenced by pH and is minimal at the isoelectric point at which the net charge is zero. Because most proteins have isoelectric points in the acidic range, this process is also called *acid precipitation.*

Precipitation is usually carried out on a small scale. Problems can arise in scaling-up this process [229]. The mixing time, the residence time in the reactor (which affects agglomerate formation and enzyme activity), and the shearing forces generated by stirring (which affect the aggregates formed) are critical parameters. When the volume being processed is large, the mixing time is appropriately long and, especially with organic solvents, protein denaturation can occur. Experiments have been conducted to overcome difficulties of this kind by using a continuous process [230].

3.2.3.3. Ultrafiltration

A semipermeable membrane permits the separation of solvent molecules from larger enzyme molecules because only the smaller molecules can penetrate the membrane when the osmotic pressure is exceeded. This is the principle of all membrane separation processes (Table 4), including ultrafiltration. In reverse osmosis, used to separate materials with low molecular mass, solubility and diffusion phenomena influence the process, whereas ultrafiltration and cross-flow filtration are based solely on the sieve effect. In processing enzymes, cross-flow filtration is used to harvest cells, whereas ultrafiltration is employed for concentrating and desalting.

Table 4. Membrane separation processes

Process	Application	Separation range, M_r
Cross-flow microfiltration	concentration of bacteria, removal of cell debris	>1 000 000 (or particles)
Ultrafiltration	concentration of enzymes, dialysis, fractionation	>10 000 (macromolecules)
Reverse osmosis	concentration of small molecules, desalting	>200

Difficulties arise from *concentration polarization.* The semipermeable membrane excludes larger molecules, which tend to accumulate near the surface of the membrane because back-diffusion into the solution is limited. As a result of the different rates of diffusion of molecules of different sizes, the separating ability of the membrane changes. Thus, the membrane holds back small molecules more strongly than would be expected from its pore size. This effect limits the applicability of membrane separation. The formation of *gel layers* on the membrane is reduced by maintaining a turbulent flow or a laminar flow with high flow rate. Loss of permeability is also caused by *membrane fouling* or *deposition* on the membrane. In particular, antifoaming agents from fermentation solutions are deposited on the membrane and make concentration of enzymes more difficult.

Membranes are available for ultrafiltration which exclude molecules ranging from 1000 to 300 000 dalton [231], [232]. Anisotropic membranes consisting of a very thin membrane layer (0.1 – 0.5 µm) and a thicker, porous support layer [233] are generally used. The different membranes employed are flat membranes (plate and frame, cassette type, or spiral winding module), hollow fibers, and tubular modules (Fig. 20). Cellulose acetate [9004-35-7] and organic polymers such as polysulfone [25135-51-7], poly(vinylidene fluoride) [24937-79-9], and polypropylene [9003-07-0] have proved to be useful as membrane materials. With the exception of cellulose acetate, these membranes can be cleaned easily with alkali or acid and steam sterilized.

Figure 20. Principles of conventional, dead end filtration (A) and cross-flow filtration (B) [Full View]

Desalting. The desalting of enzyme solutions can be carried out conveniently by diafiltration. The small salt molecules are driven through a membrane with the water molecules. The permeate is continuously replaced by fresh water. In fact, the concentration of salt decreases according to the following formula:

$$\ln \frac{c_0}{c} = \frac{V}{V_0}$$

where

c_0 = starting salt concentration

c = final salt concentration

V_0 = starting volume

V = volume exchanged

Hence, a 99 % salt exchange can be achieved when the permeated volume is $5 \cdot V_0$, independent of the starting concentration.

3.2.4. Purification

For many industrial applications, partially purified enzyme preparations will suffice; however, enzymes for analytical purposes and for medical use must be highly purified. Special procedures employed for enzyme purification are crystallization, electrophoresis, and chromatography.

3.2.4.1. Crystallization

The rapid growth in the utilization of enzymes in commercial sectors such as agriculture and consumer products requires a cost-effective, industrial-scale purification method. Crystallization, one of the oldest chemical purification technologies, has the potential to fulfill these requirements. Enzyme crystallization is the formation of solid enzyme particles of defined shape and size. An enzyme can be induced to crystallize or form protein-protein interactions by creating solvent conditions that result in enzyme supersaturation. The theory and history of protein crystallization are well documented [234-237]. Despite its history extending more than 160 years, much of the emphasis in enzyme crystallization has focused on obtaining crystals for X-ray diffraction analysis rather than as a purification process.

However, many reports of enzyme crystallization from bulk fermentation for the purpose of purification have been published [238-240]. Enzymes that have been crystallized for commercial production include a cellulase [241], [242], glucose isomerase [243] subtilisin [243], [244], and alcohol oxidase [245].

Figure 21 shows the steps involved in the crystallization process for an industrial enzyme [244]. Typical crystallization process volumes can be as large as several thousands of liters of impure enzyme solution as the starting material. The desired characteristics of industrial scale enzyme crystallization are product purity, process yield, ease of crystal recovery, and short overall process time. To achieve these aims, the crystallization process must be carefully designed and developed to produce crystals with relatively large size and desired morphology.

Figure 21. Industrial-scale halide salt crystallization of subtisilin [244]
[Full View]

Many factors, including salt type and concentration, pH, temperature, the presence of variable amounts and types of impurities, mixing, and crystal seeding, can affect enzyme crystallization. Controlling the level of supersaturation throughout the crystallization process is essential for optimization of crystal size, which can be controlled by use of precipitants such as salt, pH, and temperature [235], [246]. Temperature plays a key role in the rate of enzyme crystallization. Cellulase [241], [244] and subtilisin [247], [248] were both reported to crystallize at a much higher rate with increasing temperature.

Some enzymes can be made to grow in a variety of different morphologies by simply changing the crystallization conditions during the course of crystallization. Subtilisin was shown to form rectangular plate-shaped crystals by first nucleating at low temperature followed by growing the crystals at elevated temperature. The rectangular plate-shaped crystal is a hybrid morphology between its high- and low-temperature morphologies, rods and square plates, respectively [248].

3.2.4.2. Electrophoresis

Electrophoresis is used to isolate pure enzymes on a laboratory scale. Depending on the conditions, the following procedures can be used: *zone electrophoresis*, *isotachophoresis*, or *porosity gradients*. The heat generated in electrophoresis and the interference caused by convection are problems associated with a scale-up of this method. An interesting contribution to the industrial application of electrophoresis is a continuous process in which the electrical field is stabilized by rotation [249], [250].

3.2.4.3. Chromatography

Chromatography is of fundamental importance to enzyme purification (Table 5). Molecules are separated according to their physical properties (size, shape, charge, hydrophobic interactions), chemical properties (covalent binding), or biological properties (biospecific affinity).

Table 5. Chromatographic methods

Type of chromatography	Principle	Separation according to
Adsorption	surface binding	surface affinity
Distribution	distribution equilibrium	polarity
Ion exchange	ion binding	charge
Gel filtration	pore diffusion	molecular size, molecular shape
Affinity	specific adsorption	molecular structure
Hydrophobic	hydrophobic chelation	molecular structure
Covalent	covalent binding	polarity
Metal chelate	complex formation	molecular structure

In *gel chromatography* (also called *gel filtration)*, hydrophilic, cross-linked gels with pores of finite size are used in columns to separate biomolecules. Concentrated solutions are necessary for separation because the sample volume that can be applied to a column is limited to ca. 10 % of the column volume. In gel filtration, molecules are separated according to size and shape. Molecules larger than the largest pores in the gel beads, i.e., above the exclusion limit, cannot enter the gel and are eluted first. Smaller molecules, which enter the gel beads to varying extent depending on their size and shape, are retarded in their passage through the column and eluted in order of decreasing molecular mass. The eluation volume of a globular protein is proportional to the logarithm of its molecular mass [251]. By varying the degree of cross-linking, gels of different porosities and with different fractionation ranges are obtained. Media that collectively cover all molecular sizes are available (Table 6). These include different types of Sephadex, which can be obtained by cross-linking dextran [9004-54-0] with epichlorohydrin [106-89-8], and Sephacryl, which is prepared by cross-linking allyldextran with *N,N´*-methylene-bisacrylamide [110-26-9]. Gel filtration is used commercially for both separation and desalting of enzyme solutions.

Table 6. Gel filtration media

Trade name (manufacturer)	Matrix	Fractionation range, M_r
Biogel (Bio-Rad)	polyacylamide (P-type)	100 – 400 000
	agarose (A-type)	$1000 – 150 \times 10^6$
Ultrogele (LKB)	agarose / polyacrylamide	$60\,000 – 1.3 \times 10^6$
	agarose	$25\,000 – 20 \times 10^6$
Fractogel (Merck)	vinyl polymer (various types)	$100 – 5 \times 10^6$
Sephadex (Pharmacia)	dextran (various types)	50 – 600 000
Sepharose	agarose	$10\,000 – 40 \times 10^6$
(Pharmacia)	cross-linked agarose	$10\,000 – 40 \times 10^6$
Sephacryl (Pharmacia)	sephacryl / bisacrylamide	$5000 – 1 \times 10^6$
Glycophase	surface-modified glass	1000 – 350 000

(Pierce)	(1,2-dihydroxypropyl-substituted)

Ion-exchange chromatography is a separation technique based on the charge of protein molecules. Enzyme molecules possess positive and negative charges. The net charge is influenced by pH, and this property is used to separate proteins by chromatography on anion exchangers (positively charged) or cation exchangers (negatively charged) (Table 7). The sample is applied in aqueous solution at low ionic strength, and elution is best carried out with a salt gradient of increasing concentration. Because of the concentrating effect, samples can be applied in dilute form.

Table 7. Ion-exchange resins

Trade name (manufacturer)	Matrix	Anion-exchange groups**	Cation-exchange groups**
Cellex (Bio-Rad)	cellulose	DEAE ECTEOLA QAE TEAE	CM phosphoryl
Bio-Gel A (Bio-Rad)	agarose	DEAE	CM
Trisacryl (LKB)	synthetic polymer	DEAE	CM
Fractogel (Merck)	vinyl polymer	DEAE	CM SP
Sephadex (Pharmacia)	dextran	DEAE QAE	CM SP
Sepharose (Pharmacia)	agarose	DEAE	CM
Sepharose FF *			
Q-Sepharose			
S-Sepharose			
Sephacel (Pharmacia)	cellulose	DEAE	

* FF = fast flow.

** CM = carboxymethyl: $–O–CH_2–COO^- Na^+$; DEAE = diethylaminoethyl: $–O–CH_2–CH_2–N^+(C_2H_5)_2H\ OH^-$; ECTEOLA = mixture of different amines; QAE = 2-hydroxypropylamine: $–O–CH_2–CH_2–N^+(C_2H_5)_2–CH(OH)–CH_3\ Br^-$; SP = sulfopropyl: $-O-CH_2-CH_2-CH_2-SO_3^-Na^+$; TEAE = triethylaminoethyl: $–O–CH_2–CH_2–N^+(C_2H_5)_3\ Br^-$.

The ability to process large volumes and the elution of dilute sample components in concentrated form make ion exchange very useful. The matrix used to produce ion-exchange resins should (1) be sufficiently hydrophilic to prevent enzyme denaturation and (2) have a high capacity for large molecules at fast equilibration. In addition, industrial applications require ion exchangers that give good resolution, allow high flow rates to be used, suffer small changes in volume with salt gradients or pH changes, and can be completely regenerated.

For *hydrophobic chromatography*, media derived from the reaction of CNBr-activated Sepharose with aminoalkanes of varying chain length are suitable [252]. This method is based on the interaction of hydrophobic areas of protein molecules with hydrophobic groups on the matrix. Adsorption occurs at high salt concentrations, and fractionation of bound substances is achieved by eluting with a negative salt

gradient. This method is ideally suited for further purification of enzymes after concentration by precipitation with such salts as ammonium sulfate.

In *affinity chromatography*, the enzyme to be purified is specifically and reversibly adsorbed on an effector attached to an insoluble support matrix. Suitable effectors are substrate analogues, enzyme inhibitors, dyes, metal chelates, or antibodies. The principle of affinity chromatography is shown in Figure 24. The insoluble matrix (C) is contained in a column. The biospecific effector, e.g., an enzyme inhibitor (I), is attached to the matrix. A mixture of different enzymes (E_1, E_2, E_3, E_4) is applied to the column. The immobilized effector specifically binds the complementary enzyme. Unbound substances are washed out, and the enzyme of interest (E_1) is recovered by changing the experimental conditions, for example by altering pH or ionic strength.

[Full View]

Metal ions can also serve as effectors. They are attached to the matrix with the help of complexing agents, e.g., iminodiacetic acid [142-73-4]. Here, enzymes are separated on the basis of differing strengths of interaction with metal ions [253].

Immunoaffinity chromatography occupies a unique place in purification technology. In this procedure, monoclonal antibodies are used as effectors. Hence, the isolation of a specific substance from a complex biological mixture in one step is possible. In this procedure, enzymes can be purified by immobilizing antibodies specific for the desired enzyme. A more general method offers the synthesis of a fusion protein with protein A by “protein engineering.” Protein A is a *Staphylococcus* protein with a high affinity for many immunoglobulins, especially of the IgG class of antibodies. In this way, enzymes that usually do not bind to an antibody can be purified by immunoaffinity chromatography.

Covalent chromatography differs from other types of chromatography in that a covalent bond is formed between the required protein and the stationary phases. The principle is illustrated in Figure 25 for an enzyme containing a reactive mercapto group, such as urease (E.C. 3.5.1.5) [9002-13-5] [254].

Industrial-Scale Chromatography. The main applications of industrial-scale chromatography in the 1960 s were the desalination of enzyme solutions by use of highly cross-linked gels such as Sephadex G-25 and batch separations by means of ion exchangers such as DEAE-Sephadex A-50. The stability and hydraulic properties of chromatographic media have been improved so that these techniques are now used on a production scale. Important parameters for the scale-up of chromatographic systems are the height of the column, the linear flow rate, and the ratio of sample volume to bed volume [255]. Zone spreading interferes with the performance of the column. Factors that contribute to zone spreading are longitudinal diffusion in the column, insufficient equilibration, and inadequate column packing. Longitudinal diffusion can be minimized by using a high flow rate. On the other hand, equilibration between the stationary and the mobile phases is optimal at low flow rates. Because good process economy depends to a large extent on the flow

rate, a compromise must be made. In addition, the flow rate is also dependent on particle size; the decisive factor is usually the pressure drop along large columns. Although optimal resolution is obtained only with the smallest particles, the gel must have a particle size that favors a good throughput and reduces processing times. The use of *segmented columns* prevents a large pressure drop in the column (Fig. 26) [256]. Above all, the column must be uniformly packed so that the particle-size distribution, porosity, and resistance to flow are the same throughout the column. If this is not done, viscous protein solutions can give an uneven elution profile, which would lead to zone bleeding. The design of the column head is important for uniform distribution of the applied sample. This is generally achieved by symmetrical arrangement of several inlets and perforated inserts for good liquid distribution. The outlet of the column must have minimal volume to prevent back-mixing of the separated components.

Figure 26. Affinity chromatography

For explanation of abbreviations, see text
[Full View]

Columns of glass, plastic, or in the case of large columns, metal (stainless steel) can be used. Metal columns are usually highly polished because a smooth surface is more resistant to corrosion. Viton or poly (tetrafluoroethylene) (PTFE) is applied as sealing material. Polyethylene tubing can be used to connect small columns. Larger tubing, with a diameter of more than 4 mm, must be made of metal, with special screw connections. No dead angles should be present in which liquid can collect and cause contamination by microbial growth.

Figure 27 shows a typical industrial chromatographic column. To avoid contamination of the column, sterile filters are placed at the entrance and exit. Optimal and efficient production systems not only must meet official standards such as those of the Food and Drug Administration (FDA) or Bundesgesundheitsamt (BGA), but must also comply with rules of good manufacturing practice (GMP), which makes cleaning-in-place (CIP) necessary. The system must be operated so that impurities from the process or from microbial growth can be removed completely. Chromatographic columns can be cleaned only by washing with chemicals. The reagents used for this purpose are described in Table 8. Figures 28 and 29 show the steps involved in processing extracellular and intracellular enzymes, respectively.

Table 8. Reagents for cleaning-in-place (CIP) of chromatographic media

3.2.5. Product Formulation

Enzymes are sold as stabilized liquid concentrates or as particulate solids. The primary task of formulation is to minimize losses in enzymatic activity during transport, storage, and use. Enzymes are often exposed to humid, hot, or oxidative environments in industrial applications such as detergents, textile formulations, and food and beverage processing. Much can be done at the screening or research stage to identify enzymes that are structurally more stable or resistant to oxidation; chemical stabilizers can do little to protect thermally or chemically labile enzymes [257].

Formulations enhance stability by counteracting the primary forces of deactivation: denaturation, catalytic-site deactivation, and proteololysis [258]. Denaturation occurs by physical unfolding of an enzyme's tertiary protein structure under thermal or chemical stress. Once an enzyme begins to unfold it becomes dramatically more vulnerable to deactivation and proteolysis. To minimize unfolding, the formulator can alter the protein's environment so as to induce a compact protein structure; this is done most effectively by “preferential exclusion” of water from the protein surface by adding water-associating compounds such as sugars, polyhydric alcohols, and lyotropic salts [259]. The best ways to combat active site inactivation are to ensure sufficient levels of any required cofactors, to add reversible inhibitors, and to exclude oxidizing or reactive species from the formulation.

Besides enzymatic stability, a formulation should meet several key secondary requirements, including preservation against microbial contamination, avoidance of physical precipitation or haze formation, minimizing the formation of sensitizing dusts or aerosols, and the optimization of esthetic criteria such as color and odor. Many of these problems are best addressed by focusing as far “upstream” as possible, including the choice of raw materials in the fermentation or enzyme recovery process. Downstream operations such as diafiltration, adsorption, chromatography, crystallization, and extraction can be used to remove impurities responsible for color, odor, and precipitation [260]. The risk of physical precipitation is minimized by formulating near the isoelectric point of the enzyme with hydrophilic solvents such as glycerol or propylene glycol. One can effectively also add moderate levels of of solvating salts to avoid either salting-out or “reverse salting-in”. To prevent microbial contamination, one can use a combination of filtration, acidification, and the minimization of free water; biocides can be effective, but the range of

acceptable chemicals for controlling or killing microbes is increasingly circumscribed by health and safety regulations.

Worker safety has been a primary driver in the development of dry granular enzyme formulations for powdered laundry detergents and textile formulations. Since the 1970s, enzyme granules have become increasingly resistant to physical breakage and formation of airborne dusts upon handling. Two processes producing the most attrition-resistant granules to date are high-shear granulation and fluidized-bed spray coating. These processes use various binders, coatings, and particle morphologies to produce nonfriable particles which still protect enzymes during storage but allow for their ready release in solution during application.

3.2.6. Waste Disposal

Because of the generally low concentration of enzyme in the starting material, the volume of material that must be processed is large, and substantial amounts of waste accumulate. The spent fermentation medium can still contain large amounts of unused nutrients. However, recycling is generally not possible because of the presence of metabolites in the medium. Solid organ remains and mycelium, which are used as animal feed, can be separated. The latter must be carefully checked for undesired metabolites, e.g., antibiotics, before being fed to animals.

In recombinant DNA techniques, the need to maintain absolute containment is of great concern. Waste must be chemically or thermally inactivated before disposal, to ensure that no live organisms escape into the environment.

3.3. Immobilization

Synthesis, decomposition, and partial conversion of different compounds in biological systems are catalyzed by enzymes, water-soluble globular proteins. The catalytic activity of enzymes is brought about by their tertiary and quaternary (oligomeric enzymes) structures. All enzymes have a catalytic center, one or several substrate binding sites, and one or several regulatory sites.

The characteristics of enzymes as catalysts are (1) enzymes are able to catalyze reactions at ambient temperature and pressure and in a pH range around neutral, and (2) enzymes have strict substrate specificity, stereospecificity, regiospecificity, and reaction specificity. These facts suggest that energy-saving, resource-saving, and low-pollution processes could be designed by using enzymes, because such processes would operate at relatively low temperature and atmospheric pressure with little byproduct formation. However, the molecular structure of enzymes that is essential for their catalytic activity is liable to be destroyed under conditions such as high temperature, high or low pH, presence of organic solvents, or even conditions suitable for catalysis. The recovery of active enzymes from spent reaction mixtures is another problem when free (nonimmobilized) enzymes are used. Immobilization is one way of eliminating some of the disadvantages inherent to enzymes.

Therefore, the immobilization of biocatalysts – not only enzymes but also cellular organelles, microbial cells, plant cells, and animal cells – is attracting worldwide attention in the practical application of bioprocesses. In general, immobilized biocatalysts are stable and easy to handle compared to their free counterparts. One of their most important features is that they can be used repeatedly in a long-term series of batchwise reactions or continuously in flow systems. At present, applications of immobilized biocatalysts include (1) the production of useful compounds by stereospecific or regiospecific bioconversion, (2) the production of energy by biological processes, (3) the selective treatment of specific pollutants to solve environmental problems, (4) continuous analyses of various compounds with a high sensitivity and a high specificity, and (5) medical uses such as new types of drugs for enzyme therapy or artificial organs.

These processes require the immobilization not only of single enzymes but also of several different enzymes, organelles, or cells that catalyze more complex reactions. Various methods have been developed for the immobilization of biocatalysts, and they are being used extensively today.

3.3.1. Definitions

Immobilized enzymes are defined as “enzymes physically confined or localized in a certain defined region of space with retention of their catalytic activities, which can be used repeatedly and continuously” [261]. This definition is applicable to enzymes, cellular organelles, microbial cells, plant cells, and animal cells,

that is, to all types of biocatalysts. In some cases, these biocatalysts are bound to or within insoluble supporting materials (*carriers*) by chemical or physical binding. In other cases, biocatalysts are free, but confined to limited domains or spaces of supporting materials (*entrapment*).

The European Federation of Biotechnology, Working Party on Applied Biocatalysis (formerly, the Working Party on Immobilized Biocatalysts) has proposed that immobilized cells should be classified as *viable* and *nonviable*, where viable includes *growing* and *nongrowing* or *respiring.* According to the same definition, the terms *dead, resting*, and *living* should not be used [262]. However, in this section, the terms *treated, resting*, and *growing* — and in some cases, *living* — are used for classifying the condition of immobilized cells. Treated cells are subjected to chemical or physical treatment before or after immobilization, and resting cells do not show growth during utilization.

3.3.2. History

In 1916, NELSON and GRIFFIN observed that yeast invertase (E.C. 3.2.1.26) [9001-57-4] adsorbed on charcoal was able to catalyze the hydrolysis of sucrose [263]. After that, several reports were published on the immobilization of physiologically active proteins by covalent binding on several supports. However, immobilized enzymes were not used in practice until 1953, when GRUBHOFER and SCHLEITH immobilized several enzymes, such as carboxypeptidase, diastase, pepsin, and ribonuclease, on diazotized polyaminostyrene resin by covalent binding [264]. Thereafter, MITZ reported the ionic binding of catalase (E.C. 1.11.1.6) [9001-05-2] on DEAE-cullulose in 1956 [265]. BERNFELD and WAN described the entrapment of trypsin (E.C. 3.4.21.4) [9002-07-7], papain (E.C. 3.4.22.2) [9001-73-4], amylase, and ribonuclease in polyacrylamide gel in 1963 [266], and QUIOCHO and RICHARDS demonstrated the cross-linking of carboxypeptidase A (E.C. 3.4.17.1) [11075-17-5] with glutaraldehyde in 1964 [267]. Microencapsulation of carbonic anhydrase (E.C. 4.2.1.1) [9001-03-0] was reported by CHANG in 1964 [268] and the preparation of liposomes containing amyloglucosidase (E.C. 3.2.1.3) [9032-08-0] by GREGORIADIS in 1971 [269]; both were used in enzyme therapy. During this pioneering period, KATCHALSKI-KATZIR and co-workers made extensive contributions to the theoretical understanding of immobilized enzymes [270].

In 1969, CHIBATA and co-workers of Tanabe Seiyaku Co., Japan, were successful for the first time in the industrial application of immobilized enzymes. Fungal aminoacylase (E.C. 3.5.1.14) [9012-37-7] was immobilized on DEAE-Sephadex through ionic binding and used for the stereoselective hydrolysis of *N*-acyl-D,L-amino acids to yield L-amino acids and *N*-acyl-D-amino acids [271]. The first industrial application of immobilized microbial cells was also performed by CHIBATA and co-workers in 1973 to produce L-aspartate from ammonium fumarate by polyacrylamide gel-entrapped *Escherichia coli* cells containing a high activity of aspartase (E.C. 4.3.1.1) [9027-30-9]. Other processes that have been industrialized use immobilized enzymes and microbial cells. They are discussed briefly in Section Application.

3.3.3. Methods

For the application of immobilized biocatalysts, their screening to the desired activity and characteristics is most important. In addition, selection of the appropriate combination of supporting material and immobilization method, both of which should be suitable for each biocatalyst, is necessary. No systematic concept is available at present for design of the most appropriate method of immobilization for various biocatalysts. Optimization is carried out in general by trial and error.

At present, various immobilization techniques are available [272], and Figure 30 illustrates the principles of these methods. Because each method has its own merits and demerits, selection should be based on the intended purpose, including type of biocatalyst, type of reaction, and type of reactor.

Figure 30. Isolation of extracellular enzymes

[Full View]

Supporting materials should have adequate functional groups to immobilize the biocatalysts, as well as sufficient mechanical strength; physical, chemical, and biological stability; and nontoxicity. Easy shaping is

also important for applying immobilized biocatalysts to different types of reactors. Furthermore, the economic feasibility should be examined. Some supporting materials are described in the following sections.

3.3.3.1. Carrier Binding

Enzyme proteins have amino acid residues containing chemically reactive groups, ionic groups, and/or hydrophobic groups, as well as hydrophobic domains. These amino acid residues and the hydrophobic domains can participate in the immobilization of enzymes through covalent linkage, ionic binding, or physical adsorption. Various types of insoluble supports (carriers) are utilized as is or after proper modification or activation.

Covalent Binding. Amino acid residues that are not involved in the active site or substrate-binding site of the enzymes to be immobilized can be used for covalent binding with supports. These are the ε-amino group of lysine, the mercapto group of cysteine, the β-carboxyl group of aspartic acid, the γ-carboxyl group of glutamic acid, the phenolic hydroxyl group of tyrosine, or the hydroxyl groups of serine and threonine. Hydroxyl, carboxyl, and amino groups are especially excellent targets because of their relative abundance in enzyme molecules.

Enzymes immobilized by covalent binding have the following advantages: (1) because of the tight binding, they do not leak or detach from supports during utilization; (2) immobilized enzymes can easily come into contact with substrates because the enzymes are localized on the surface of supports; and (3) an increase in heat stability is often observed because of the strong interaction between enzyme molecules and supports.

On the other hand, disadvantages of covalent binding are: (1) active structures of enzyme molecules are liable to be destroyed by partial modification; (2) strong interaction between enzyme molecules and supports often hinders the free movement of enzyme molecules, resulting in decreased enzyme activity; (3) optimal conditions of immobilization are difficult to find; (4) this method is not suitable for immobilization of cells; and (5) supports, in general, are not renewable. Hence, this principle is well-suited to expensive enzymes whose stability is significantly improved by covalent binding.

Despite these disadvantages, covalent binding is often applied to the preparation of immobilized enzymes for analytical purposes. Some typical examples of covalent binding methods are described below, but many other techniques have also been reported.

Cyanogen Bromide. The cyanogen bromide method was first demonstrated by AXÉN and his co-workers [273]. It involves the activation of supports having vicinal hydroxyl groups (**1**), such as polysaccharides, glass beads, or ceramics, with cyanogen bromide [506-68-3] (**2**), to yield reactive imidocarbonate derivatives (**3**). The subsequent reaction between the activated supports and enzyme molecules gives *N*-substituted isourea (**4**), *N*-substituted imidocarbonate (**5**), and *N*-substituted carbamate derivatives (**6**).

This method has been widely used for the immobilization of various enzymes, and CNBr-activated supports, such as CNBr-activated Sepharose, are available. Aminated glass beads and aminated polyacrylamide gel are also used as supports in this method. The insertion of spacers such as hexamethylenediamine [124-09-4] is also possible, to avoid strong interaction between enzyme molecules and supports.

Acid Azide Derivatives. The acid azide method, which is used for peptide synthesis, is also applicable to the immobilization of various enzymes [274]. For example, carboxymethyl cellulose [9004-42-6] (**7**) is converted to the methyl ester (**8**) and then to the hydrazide (**9**) with hydrazine. The hydrazide reacts with nitrous acid to form the azide derivative (**10**), which can then react with enzyme molecules at low temperature to yield immobilized enzymes (**11**). Several supports containing carboxyl groups can be used for this method.

Condensing Reagents. Carboxyl groups or amino groups of supports and amino groups or carboxyl groups of enzyme molecules can be condensed directly through the formation of peptide linkages by the action of carbodiimide reagents or Woodward's reagent K (*N*-ethyl-5-phenylisoxazolium-3′-sulfonate) [4156-16-5]. Carboxymethyl cellulose is one of the supports used for this method [275].

Diazo Coupling. Supports having aromatic amino groups (**12**) are diazotized with nitrous acid to form the diazonium derivatives (**13**), which react with enzyme molecules to yield immobilized enzymes (**14**). 4-Aminobenzyl cellulose [9032-51-3] [276] and polyaminostyrene [9060-90-6] [277] are typical supports used for this method.

Alkylation. Alkylation groups on supports can easily react with amino groups, phenolic hydroxyl groups, and sulfhydryl groups of the enzyme molecules. For example, halogenated acetyl cellulose (**15**) [278] and triazinyl derivatives of ion-exchange resins (**16**) or cellulose [279] may be used for this method.

Carrier Cross-linking. Supports and enzyme molecules can be cross-linked with bi- or multifunctional reagents. For example, aminoethyl cellulose [9032-36-4] (**17**) and amino groups of enzyme molecules are combined through Schiff's base linkage (**19**) with glutaraldehyde [111-30-8] (**18**) [280]. Diisocyanates represent another group of cross-linking reagents. Several supports containing amino groups are also employed.

Ionic Binding. Since catalase was found to be bound to ion-exchange cellulose [265], this method has been applied for the immobilization of many enzymes, because the procedure is very simple, the supports are renewable, and the enzymes are not modified. The most notable example is the production of L-amino acids by aminoacylase (E.C. 3.5.1.14) [9012-37-7] immobilized on DEAE-Sephadex [271]. Binding of enzymes on supports is affected by the kind of buffers used, pH, ionic strength, and temperature. Several derivatives of cellulose and Sephadex, as well as various ion-exchange resins, can be utilized for immobilization.

Physical Adsorption. Biocatalysts often bind to carriers by physical interaction such as hydrogen bonding, hydrophobic interaction, van der Waal's forces, or their combined action. Although biocatalysts are immobilized without any modification, interaction between biocatalyst and support is generally weak and affected by such environmental conditions as temperature or concentration of reactants. Various inorganic supports are often used. Several synthetic resin beads and natural materials (e.g., chitosan beads with micropores of controlled size) having strong adsorption capacities are available. Adsorption followed by cross-linking with glutaraldehyde sometimes stabilizes the activity of immobilized enzymes. Phenoxyacetylated cellulose and glass beads are used as specific supports of a hydrophobic nature. Tannins, which interact strongly with proteins, are also applied as ligands after appropriate immobilization. Cellular organelles and various types of cells can be immobilized by physical adsorption. Supports are renewable under appropriate conditions.

3.3.3.2. Cross-linking

Bi- and multifunctional compounds serve as reagents for intermolecular cross-linking of enzymes. Cross-linked enzymes are then insoluble macromolecules. In addition to glutaraldehyde [111-30-8] (**20**) [267] which is the most popular cross-linking reagent, several compounds such as toluene diisocyanate [1321-38-6] or hexamethylene diisocyanate [822-06-0] (**21**) are used. The yield of enzyme activity is usually low. Microbial cells are also cross-linked with glutaraldehyde to yield cell pellets.

3.3.3.3. Entrapment

Entrapped biocatalysts are classified according to the following different types:

Lattice type: biocatalysts entrapped in gel matrices prepared from polysaccharides, proteins, or synthetic polymers.

Microcapsule type: biocatalysts entrapped in microcapsules of semipermeable synthetic polymers.

Liposome type: biocatalysts entrapped within liquid membranes prepared from phospholipids.

Hollow-fiber type: biocatalysts separated from the environment by hollow fibers.

Membrane type: biocatalysts separated from the spent reaction solution by ultrafiltration membranes.

The advantages of entrapping methods are that not only single enzymes but also several different enzymes, cellular organelles, and cells can be immobilized with essentially the same procedures. Biocatalysts are not subjected to serious modification, and immobilization eliminates the effect of proteases and enzyme inhibitors of high molecular mass. However, disadvantages are (1) substrates of high molecular mass can hardly gain access to the entrapped biocatalysts and (2) supports are not renewable. Entrapment within ultrafiltration membranes can avoid the disadvantages inherent in entrapping methods, although inactivated enzyme molecules often precipitate on the membrane surface, which results in decreased permeability to reaction solutions. The lattice-type method is most widely applied for preparing immobilized biocatalysts. Several examples of this technique are mentioned in the following paragraphs.

Polyacrylamide Gel. Since BERNFELD and WAN [266] reported the entrapment of several enzymes in polyacrylamide gels (**24**), different types of biocatalysts including cellular organelles and microbial cells have been immobilized by this method. This method was also applied to the industrial production of L-aspartate, L-malate, and acrylamide by immobilized microbial cells. In a typical procedure, acrylamide [79-06-1] (**22**) and *N,N′*-methylenebisacrylamide [110-26-9] (**23**) (cross-linking reagent) are mixed with biocatalysts and polymerized in the presence of an initiator (potassium persulfate [7727-21-1]) and a stimulator (3-dimethylaminopropionitrile [1738-25-6] (DMAPN) or *N,N,N′N′*-tetramethylenediamine [110-18-9]). Although this technique is used for various purposes, acrylamide monomer sometimes inactivates enzymes. Several analogues or derivatives of acrylamide can also be used in this method.

Alginate Gel. Several natural polysaccharides, such as alginate, agar, and κ-carrageenan, are excellent gel materials and used widely for the entrapment of various biocatalysts.

Sodium alginate I [9005-38-3], which is soluble in water, is mixed with a solution or suspension of the biocatalysts and then dropped into a calcium chloride solution to form water-insoluble calcium alginate gels that immobilize enzymes, cellular organelles, or microbial cells [281]. However, gels are gradually solubilized in the presence of calcium ion-trapping reagents such as phosphate ions. Aluminum ions or several divalent metal ions can be substituted for calcium.

This method is used widely for immobilization of various biocatalysts because of its simplicity and the availability of sodium alginate.

κ-Carrageenan Gel. CHIBATA and co-workers [282] have extensively screened gel materials for the immobilization of enzymes and microbial cells in industrial applications and have found κ-carrageenan (**25**) to be the best.

κ-Carrageenan in saline is mixed with a solution or suspension of biocatalysts and dropped into a solution of gelling reagent, such as potassium chloride [7447-40-7] [283]. Various cations, such as ammonium, calcium, and aluminum, also serve as good gelling reagents. Hardening of gels with glutaraldehyde and hexamethylenediamine often stabilizes the biocatalysts entrapped in κ-carrageenan gels.

This method has replaced polyacrylamide gels in the industrial production of L-aspartate [284] and L-malate

[285] by means of immobilized microbial cells.

κ-Carrageenan gels can be solubilized in saline or in water, which enables the number of cells in the gel to be counted.

Synthetic Resin Prepolymers. With the application of a variety of bioreactions, including synthesis, transformation, degradation, or assay of various compounds having different chemical properties, entrapment of biocatalysts in gels of controlled physicochemical properties has become desirable. Selection of suitable gels and modification of natural polymers to meet each purpose are usually difficult. For these reasons, a new entrapping method using synthetic resin prepolymers has been developed by FUKUI and co-workers [286].

Specific features and advantages of the prepolymer method are (1) entrapment procedures are very simple and proceed under very mild conditions; (2) prepolymers do not contain monomers that may have unfavorable effects on enzyme molecules; (3) the network structure of gels can easily be controlled by using prepolymers of optional chain length; and (4) the physicochemical properties of gels, such as the hydrophilicity – hydrophobicity balance and the ionic nature, can be changed by selecting suitable prepolymers synthesized in advance in the absence of biocatalysts.

Photo-cross-linkable resin prepolymers having hydrophilic (**26**) or hydrophobic (**27**) properties, cationic or anionic nature, and different chain lengths have been developed [286], [287].

26: R = H
27: R = CH_3

Mixtures of prepolymers and biocatalysts are gelled by irradiation with long-wavelength UV light for several minutes in the presence of a proper sensitizer such as benzoin ethyl ether [574-09-4]. This method has been applied for the pilot-scale production of ethanol by immobilized growing yeast cells.

Entrapment by urethane prepolymers (**28**) with different hydrophilicity or hydrophobicity and chain length is much simpler [286], [288]. When the liquid prepolymers are mixed with an aqueous solution or suspension of the biocatalysts, the prepolymers react with each other to form urea bonds and liberate carbon dioxide.

28

These prepolymers can immobilize not only enzymes but cellular organelles and microbial cells as well. The hydrophilicity – hydrophobicity balance of these gels has been demonstrated to affect especially the bioconversion of lipophilic compounds in organic solvent systems [289].

3.3.4. Characterization

The characteristics of immobilized biocatalysts should be described in the literature because different methods and preparations must be compared for their evaluation. However, determination of what kinds of description and what types of parameters should be given is difficult. Methods for estimating these parameters vary from group to group. Therefore, at present, the results described in the literature cannot be compared. The Working Party on Immobilized Biocatalysts within the European Federation of Biotechnology has made a proposal for the description of several properties of immobilized biocatalysts [290]. Although the proposal will be difficult to follow completely, it will be useful for the characterization of immobilized biocatalysts.

The minimum requirements recommended for characterization of an immobilized biocatalyst are as follows:

1. *General description*
   reaction scheme
   enzyme and microorganism
   carrier type
   method of immobilization
2. *Preparation of the immobilized biocatalyst*
   method of immobilization, reaction conditions, dry mass yield, activity left in supernatant
3. *Physicochemical characterization*
   biocatalyst shape, mean wet particle size, swelling behavior
   compression behavior in column systems, abrasion in stirred vessels, or minimum fluidization velocity and abrasion in fluidized beds
4. *Immobilized biocatalyst kinetics*
   Initial rates vs.
   - substrate concentration for free and immobilized biocatalyst, effect of pH and buffer
   - diffusional limitations in the immobilized biocatalyst system (effect of particle size or enzyme load on activity)
   - degree of conversion vs. residence time (points on a curve)
   - storage stability (residual initial rate after storage for different periods)
   - operational stability (residual initial rate or transforming capacity of reaction system) after operation for different periods

3.3.5. Application

Immobilized biocatalysts — enzymes, cellular organelles, microbial cells, plant cells, and animal cells — have been applied to the production or conversion of various compounds such as amino acids, peptides and enzymes, sugars, organic acids, antibiotics, steroids, nucleosides and nucleotides, lipids, terpenoids, fuels, or commodity chemicals. Some typical examples are described below.

A major industrial application of immobilized enzymes is the production of various L-amino acids, such as L-alanine, L-isoleucine, L-methionine, L-phenylalanine, L-tryptophan, and L-valine, by fungal aminoacylase (E.C. 3.5.1.14) [9012-37-7] immobilized on DEAE-Sephadex by ionic binding [271]. This enzyme hydrolyzes stereoselectively the L-isomer of *N*-acyl-D,L-amino acids (**29**) to yield L-amino acids (**30**) and unreacted *N*-acyl-D-amino acids (**31**); the latter are subsequently converted into the racemic form by heating. In this way, both the L- and D-isomers are converted completely to L-amino acids.

CHIBATA and co-workers also succeeded in producing L-aspartic acid [56-84-8] (**33**) from ammonium fumarate [14548-85-7] (**32**) by polyacrylamide gel-entrapped *Escherichia coli* cells containing a high activity of aspartase (E.C. 4.3.1.1) [9027-30-9].

An active and stable preparation was obtained (half-life, 120 d) when the immobilized cells were incubated with a substrate solution for 48 h at 30 °C [291]. This process is the first example of an industrial application of immobilized cells and the enzyme partially isolated from *E. coli* cells is not as stable even after immobilization. At present, the process can be improved by entrapping the cells in κ-carrageenan gels, followed by hardening with glutaraldehyde and hexamethylenediamine; these immobilized cells have a half-life of 680 d [284].

L-Alanine [56-41-7] (**34**) is produced from L-aspartic acid [56-84-8] (**33**) by κ-carrageenan gel-entrapped cells of *Pseudomonas dacunhae* having a high activity of L-aspartate 4-decarboxylase (E.C. 4.1.1.12) [9024-57-1] [292]. This process was commercialized in 1982 by the Tanabe Seiyaku Co. in Japan.

Immobilized penicillin acylase (amidase) (E.C. 3.5.1.11) [9014-06-6] is now widely used in the production of 6-aminopenicillanic acid [551-16-6] (**36**) from penicillin G [61-33-6] (**35**). Glucose isomerase (E.C. 5.3.1.18) [9055-00-9] is used in the production of high-fructose syrup (**38**) from glucose [50-99-7] (**37**).

A process for production of L-malate (**40**) from fumarate (**39**) has been developed by CHIBATA and co-workers by using *Brevibacterium ammoniagenes* cells containing fumarase (E.C. 4.2.1.2) [9032-88-6] entrapped in polyacrylamide gels [293].

The entrapped cells were treated with bile extract to suppress the formation of byproduct succinate, which leads to the industrial application of this system in 1974. Later *B. flavum* was substituted for *B. ammoniagenes* and κ-carrageenan gels for polyacrylamide gels. κ-Carrageenan gel-entrapped cells showed a half-life of 160 d [285].

The latest use for immobilized biocatalysts is the production of cheap commodity chemicals such as acrylamide (**42**) from acrylonitrile (**41**).

Polyacrylamide gel-entrapped cells of *Corynebacterium* species are used for the production of acrylamide at low temperature by Nitto Chemical Industry in Japan. YAMADA and his co-workers have found that in *Pseudomonas chlororaphis*, nitrile hydratase [82391-37-5] participates in this reaction [294].

In addition to the immobilized enzymes and treated cells mentioned above, other immobilized living or growing cells are now being investigated extensively for the production of more complex compounds by using the metabolic activities of these cells. Plant and animal cells as well as microbial cells are targets of immobilization because these cells have self-regenerating and self-proliferating catalytic systems [295]. Genetically improved cells are also useful biocatalysts.

Bioconversion of lipophilic compounds in organic solvent systems is another subject of interest industrially. Immobilization in or on proper supports stabilizes biocatalysts even in the presence of organic solvents [289].

Thus, the applications of immobilized biocatalysts are now expanding along with the development of immobilization techniques and the improvement of biocatalysts.

4. Discovery and Development of Enzymes

4.1. Enzyme Screening

4.1.1. Overview

Screening and selection are early processes in the research and development cycle of a product. In essence this means searching for a particular gene coding for the target enzyme. In the past this involved exclusively the screening of living microorganisms (classical microbial screening), but with the application of the modern tools of molecular biology, screening can be performed without the need to culture the organisms involved. As with all methods, there are limitations, and a combination of techniques (combinatorial screening) often provides the greatest success.

The most rewarding starting point for the process of search and discovery is the rich diversity of microorganisms in nature [296]. It is seldom appreciated that for 85 % of the Earth's history, life was restricted to microbial forms. The metabolic diversity this has created is truly immense. During more than four billion years of evolution, enzymes have emerged that are perfectly adapted for maintaining cellular processes. However, many enzymes are required to perform in a milieu that is far removed from the natural physiological conditions and may even involve exposure to chemicals known to degrade or denature enzymes, which leads to loss of activity. Usually, enzyme screening and selection strategies are based on knowledge of the application and the physical and chemical conditions under which the enzyme must operate. Therefore, selection for enzyme performance under application conditions is an essential early step in the screening process. Access to a large gene pool is another prerequisite for a successful screening program. The approaches can involve the indiscriminate examination of heterogeneous material (e.g., soil) gathered from the environment, or an ecological approach with a targeted examination of specific habitats where a particular activity is likely to be found. Strategies can be adopted to search specifically in poorly explored environments in order to access a greater variation in genomes from novel microbes. In the search for new genes, exploration of extreme environments such as volcanic hot springs, hypersaline lakes, and polar soils has yielded many novel microorganisms with peculiar properties [297-299]. Alternatively, a taxonomy-based approach involving a systematic study of known organisms can also be rewarding. By combining enzyme screening with modern techniques such as protein engineering and directed evolution, hybrid molecules with an improved performance under specific application conditions can be found. This chapter will describe the different screening methods currently used in industry to obtain enzymes with desired properties.

4.1.2. Natural Isolate Screening

The source material for enzyme discovery can be plant or animal matter and microbes, both prokaryotes (e.g., bacteria and archaea) and eukaryotes (e.g., yeasts and fungi). Microorganisms are the major source for industrial enzymes. The classical method of screening natural microbial isolates is a well-established process having its roots in antibiotic discovery (e.g., penicillins, streptomycin) in the decades after 1945. It involves the examination of thousands of samples of soils, plant material, etc., and the random isolation and screening of the resident microbial flora. Although capable of significant automation, the throughput capacity largely determines the speed of progress. In the past, screening strategies using soil samples as a starting point were highly empirical. But much can be done to reduce the need for extensive experimentation. These processes involve subjecting an environmental sample (e.g., soil) to selective pressure using the principles of enrichment culture by manipulating the growth conditions so that only microorganisms expressing a particular enzyme are able to grow and survive. For example, by providing only xylan as a source of carbon and energy, only microbes producing a xylanase constitutively or by induction will grow, and the culture

becomes enriched in these organisms. The system is capable of considerable refinement; for example, if an acidic xylanase is required, then the pH of the enrichment culture can be designed to permit growth of microbes producing the enzyme at pH 4 – 6. A successful outcome can be improved by a judicious choice of environment for examination, for example, acidic soils, peat bogs, and forest litter.

An ecological approach takes advantage of the natural selective pressure of the environment. For example, an alkaline environment such as a soda lake at pH 9 is inhabited only by alkaliphilic microorganisms. It is likely that these organisms have extracellular enzymes that are stable and perform optimally at high pH, and this is indeed the case [300]. For screening of feed enzymes such considerations are often less clear cut. What, for example, is the natural habitat for a phytase-producing microorganism? Phytate, a storage phosphate, is often a major component of some seeds, and screening microorganisms in intimate association with the roots of germinating seeds (rhizosphere) would be an appropriate niche to examine.

The time between collection of the environmental sample and its examination in the laboratory can be critical, since changes will inevitably occur. Even in the best-preserved samples, chemical and physical changes may lead to the death of some organisms and reduced viability of others. The longer the time lapse, the more serious these changes can be. There are many advantages in treating the sample immediately in the field, since this can lead to the isolation of a totally different population of microbes. It can be useful to provide “bait” for specific microbes or types of microbial activities. An example of this in situ enrichment is placing cotton linters in an environment such as lake sediment and retrieving the sample at a later date. The sample can then be taken back to the laboratory and screened for cellulolytic activity. Many other enrichment techniques have been developed empirically, such as the use of water- or chitin-agar for isolation of slow-growing actinomycetes, and such ideas are limitless [301].

In addition to enrichment for desired microorganisms, the numbers of unwanted microbes can be reduced. In fact, the first problem in processing of samples is often one of numbers. Composts and soils rich in organic matter contain enormous numbers of microbes. Some form of dilution is required, or targeting of specific groups. Selective techniques can involve, for instance, careful air-drying of the (soil) sample, which reduces the numbers of Gram-negative bacteria, or a brief heat treatment at 80 °C, which kills most microorganisms but leaves the resistant spores of bacteria such as *Bacillus* intact. Antibiotics may be incorporated into the growth medium. For example, Gram-positive bacteria are more sensitive towards penicillin than Gram-negative bacteria.

Whatever the screening strategy adopted, all these approaches rely on some form of selection criteria for the organism-activity combination being sought. The most widely applied methods involve growing the microbes on an agar plate containing the appropriate enzyme substrate for detecting the desired enzyme activity. Often the methods employed are proprietary and frequently constitute more of an art than an exact science. Some methods, however, are well understood. For instance, incorporating casein as sole carbon source into an agar medium with an opaque surface will reveal protease-secreting organisms as a clear halo of hydrolyzed casein around the growing colony. Similarly, lipase activity can be monitored by a change in color of an indicator that visualizes the drop in pH due to the release of fatty acids from a lipid substrate. Specific cleavage reactions can also be detected by release of a fluorescent product or a strongly absorbing (chromogenic) product from an appropriate substrate [302-304]. An interesting possibility is provided by display of a quenched fluorescent substrate on the cell surface of a recombinant host that after cleavage gives a fluorescent product which remains associated with the cell [305].

The selection of microorganisms is a very critical stage in the screening process and can be quite subjective, especially if the numbers involved are very large. Even though the screening has followed some form of selection process it is often not easy to distinguish the different types of microorganism growing on an agar medium. This is particularly true of bacteria, which, unless they are clearly colored, all look much the same. This gives rise to one of the biggest drawbacks of the random approach to isolation and screening of naturally occurring strains: the problem of redundancy. The same microbe will recur time and again from different samples collected from different locations, and this may explain why so many products come from a very limited range of microbes. Until relatively recently most screening strategies were fairly conservative. The tendency to use rich media that favor fast-growing, nutritionally undemanding organisms has lead to an overemphasis on particular groups of microorganisms. This is coupled to the fact that certain fungal genera such as *Aspergillus* and *Trichoderma*, and *Bacillus* and *Pseudomonas* species among the bacteria, have traditionally been a rich and proven source of commercial enzymes. To ensure greater diversity and as a

measure of how extensive a screening has been, some estimate of the biodiversity of the population screened is required. A decade ago this was a daunting task involving a detailed examination of each organism, but nowadays fast molecular methods are available. A range of techniques rapidly group collections of unknown strains into clusters of related organisms. Total cell protein patterns, amplified fragment length polymorphism, ribotyping, amplified ribosomal DNA restriction analysis, internally transcribed spacer region PCR, single-strand conformational polymorphism combined with sophisticated electrophoresis methods, and image analysis for data acquisition and computation can provide information on the diversity of a strain collection. Today, the ease with which small subunit ribosomal RNA (ssu rRNA) gene sequencing can be performed, combined with a large and growing database for comparison, means that specific organisms can often be quickly assigned to known taxonomic groups, or novel microorganisms can be recognized. The clustering of organisms into related groups of strains can be combined with screening of selection data, thus permitting the identification of specific attributes with recognized groups of organisms. This information allows one to devise particular procedures for the isolation of a specific target group and the imposition of more stringent selection criteria. Even so, it is still too easy to overlook potential novel isolates, especially when confronted by many hundreds of culture dishes, each one containing several hundred similar-looking microbial colonies. Nowadays, the task can be performed by colony-picking robots and visual imaging systems coupled to computers.

One problem often encountered early in the screening process is that natural microbial isolates usually produce commercially important enzymes in exceedingly low concentrations. Environmental manipulation that optimizes the growth and production conditions is limited by the intrinsic maximum ability of the wild-type organism. Classical genetic manipulation by selecting mutants with improved properties can lead to an increase of potential yield. The classical techniques of mutation and selection for microorganisms with improved attributes has been applied for many decades. Modern methods of molecular biology have accelerated the possibilities of creating in the laboratory microorganisms with new or improved activities.

4.1.3. Molecular Screening

If a suitable lead enzyme, for example, an acid xylanase, has been identified in a particular species then a search can be made for homologous enzymes in related species. The process requires the application of reverse genetics. Enzymes are polymers of amino acids covalently bonded in a defined sequence. The order in which the amino acids are arranged in the enzyme can be analyzed by a process known as N-terminal sequencing. Since the genetic code is universal it is possible to predict the probable sequence of nucleotide bases in the gene coding for the specific enzyme. Using this information a probe can be constructed consisting of 15 to 20 nucleotides (primer set) in the correct sequence, which, because of the double helix nature of DNA, will bind to the complementary strand. By using the primer set in the polymerase chain reaction (PCR) on chromosomal DNA from related organisms, a homologous gene can be amplified and transferred to a host organism such as *E. coli* for expression of the gene product, i.e., a homologous enzyme [306]. In practice the procedure can be a little more complex than is described here, but it is possible to track down enzymes with identical functionality (e.g., a xylanase) but with a significantly different sequence of amino acids, whereby only the crucial elements of the enzyme such as the active site have been conserved through evolution. In application tests these “new” enzymes may have significantly different properties, such as improved temperature or pH stability compared with the lead molecule. In this way whole families of related organisms can be screened. Alternatively, the microbial DNA can be probed with DNA carrying a radioactive or fluorescent label by a technique called hybridization. However, all molecular methods based on similarity screening have one big drawback. They rely on a comparison with data that has already been recorded.

4.1.4. Environmental Gene Screening

Even though molecular screening is a very powerful technique it seems limited by the ability to grow and extract suitable DNA from the target organisms. It is also confined to known microorganisms that have been isolated, described, and deposited in culture collections. However, it has been estimated that fewer than 1 % of all microorganisms that exist in nature have been isolated, and even fewer have been adequately characterized and described [307]. It is thought that fewer than 25 % of the microbes in a sample taken from the environment can actually be cultured in the laboratory. There may be many reasons for this “unculturable” portion of the microbial community. Some cells may be in a resting phase, damaged, or moribund; some may not be true residents and not form part of the active population; others may be opportunists waiting for a shift in environmental conditions in their favor; while others may have unknown requirements for culture that remain unmet in the laboratory.

Cultivation in the laboratory has a strong selective bias; the techniques are very conservative and have hardly changed for 100 years. Yet we are imprisoned within these constraints since we have no intellectual answers to this problem [308]. The main biodiversity of life is microbial, distributed among three primary relatedness groups or domains: Archaea, Bacteria, and Eukarya. The number of validly described species of prokaryotes is about 4500 and increases at a rate of 100–200 per year. In 1987, WOESE described the bacterial domain as comprised of about 12 naturally related groups (divisions) based on ssRNA sequence analysis of familiar cultivated organisms and showed that they displayed greater evolutionary depth (genetic biodiversity) than plants, animals, and fungi [309]. Phylogenetic studies of cultured and environmental sequences have since expanded substantially our appreciation of the scope of bacterial biodiversity. Three trail-blazing, seminal research reports, all published in 1990, indicated that bacterial biodiversity based on molecular studies was significantly larger than that known from pure cultures. From a DNA-DNA reassociation study it was estimated that a single sample of forest soil contains about 12 000 bacterial species [310]. The other two studies reported cultivation-independent retrieval of partial 16S rDNA sequences from marine bacterioplankton [311] and hot springs [312]. The retrieved 16S rRNA sequences did not match those of known cultured bacteria and thereby provided evidence for numerous as yet unknown bacteria. A more recent examination of environmental DNA derived from diverse habitats revealed, in addition to a vast biodiversity of yet to be cultivated microorganisms, that the cultivated microorganisms may not be the dominant flora in these environments, and this provides a further challenge to the screening by enrichment culture methods [313, 314]. Now, after nearly a decade of direct rRNA sequence retrieval from the natural environment, nearly 40 distinct bacterial divisions (kingdom-level phylogenetic divergences) are resolved. Just four of these divisions account for 90 % of all cultivated bacteria (Proteobacteria, Cytophaga-Flavobacterium-Bacteroides, and the high and low G+C Gram-positives). It is small wonder that most microbial biotechnology is devoted to organisms that fall into these groups. For over 15 of the bacterial divisions, not a single organism in culture is known, and for a further 15 divisions one or two cultured representatives are supported only by the environmental sequence footprint [315]. The phylogenetic differences between the bacterial divisions are probably reflected in substantial physiological differences [316].

Fortunately recent technological developments have permitted access to at least a portion of these uncultivated microbes [313, 317]. It is possible to extract DNA or even RNA directly from the microbial community present in a sample taken from the environment. Although there are many techniques for extracting chromosomal DNA from natural microbial communities, not all cells are equally susceptible to lysis, and the DNAis never recovered to 100 %. Another concern is the detection of organisms that form only a minor proportion of the total community. Their DNA will be under-represented unless efforts are made to normalize the sample. The environmental DNA can be tested for known genes by using the molecular techniques described above. This requires good quality DNA, since PCR screening is particularly sensitive to disturbance by contaminating substances in the environment. Alternatively, the environmental DNA can be cut into smaller fragments by using restriction enzymes, and the fragments cloned into an expression host such as *E. coli*. Likewise, environmental RNA can be used to construct cDNA expression libraries. The clones can then be screened for new enzyme-encoding genes in a manner similar to many of the techniques described for the screening of natural microbial isolates thus allowing the detection of desired activities encoded by genes that might show only limited or no similarity at all to known genes.

4.1.5. Genomic Screening

Spectacular progress has been made in the direct sequencing of the nucleotides of a DNA strand. Already there are millions of gene sequences in public databases. The whole genomes of over 800 organisms can be found in public databases such as Entrez Genomes [`http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Genome`]. The genomes represent both completely sequenced organisms and those for which sequencing is in progress. All three main domains of life — bacteria, archaea, and eukaryota — are represented, as well as many viruses and organelles. At present (2003) 80 prokaryotic (66 bacteria and 13 archaea) genomes and several microbial eukaryotic genomes have been sequenced in their entirety, and the sequencing of more than 120 microbial genomes is in progress. Random shotgun sequencing allows rapid elucidation of microbial genomes [318], and technical advances are expected to further accelerate genome sequencing. Originally, pathogenic species were the main focus of microbial sequencing projects, but many microbes with industrial potential are being sequenced as well. For example, the genomes of thermophilic, alkaliphilic, acidophilic, and salt-tolerant microbes have been sequenced [319-323]. This illustrates the general belief that genome analysis will reveal

the mechanisms underlying the respective lifestyles of these microbes, aid in identifying industrially relevant extremophilic enzymes, and possibly allow the recognition of general protein rules that result in enzymatic performance under extreme conditions. Global analysis of thermophilic proteins shows, for instance, a tendency to reduced protein size; increased hydrogen bonding, beta-strand content, and helix stabilization through ion pairs; and preference for charged residues over uncharged polar residues [319], [324], [325].

When a microbial genome sequence is available, protein-coding genes can be identified computationally by essentially two different methods [326]. Ab initio searches use a template that integrates general knowledge about gene composition and signals to find novel genes. A more reliable computational method uses similarity to a protein-coding gene in another organism to identify novel genes. The latter method depends, however, on the availability of homologous genes, but it has as added benefit the ability to indicate gene function. Since prokaryotic genes frequently overlap with each other, exact prediction is notoriously difficult, and as a result the true number of protein-coding genes for sequenced microbial genomes remains debatable [327], [328]. A further complication that adds to the discrepancy between gene predictions and expressed proteins is presented by alternative splicing, which can occur in microbial eukaryotes [329]. Several experimental approaches, such as EST sequencing and scanning-tiling microarray analysis, allow validation of computationally identified genes [330].

The enormous amount of sequence data in the public domain has driven the emergence of bioinformatics, which can be defined as the interface between biological and computational sciences. Bioinformatics uses computational tools to organize and analyze biological data and aims to extract biological information and knowledge. Typical examples include identification of homologous genes or specific protein domains and transfer of functional knowledge associated with these homologues or domains to predict function for the new genes [331-333]. For example, similarity searching at the gene level allows in silico screening for enzymes [334]. Note, however, that sequence data are certainly not flawless, and a considerable error rate should therefore be considered in the analysis [331], [335]. Error frequency can be reduced by integration of additional information that can be extracted from genomic or experimental data [336]. Other computational methods that make use of available genomic sequences to infer function rely on, e.g., genomic clustering of functionally related genes [337], [338], phylogenetics [339], [340], metabolic pathway alignment [341], [342], and combined approaches [343]. Despite such powerful tools, about 25 % of the putative genes revealed by total genome sequencing projects cannot currently be assigned a function because they only show homology to other unannotated genes. Another 25 % of the genes are of unknown function and seem to be unique to their particular species [344]. These data indicate that the resources for screening of novel enzymes are still largely untapped. Sparked by these findings several new high-throughput experimental technologies have been developed that aim to identify functions for these orphan genes.

Many methods have been developed that use loss of function, cellular localization, protein interaction, or timing of expression to predict function for novel proteins and can be claimed as tools for so-called functional genomics. Essentially, most of these methods infer function indirectly as “guilt by association” in time or space with characterized proteins. For example, a wide variety of techniques are available to disrupt genes, random or directed, on a large scale in virtually any organism (Hensel and Holden, 1996; [345-350]). Subsequent phenotypic analysis, quite similar to natural isolate screening, allows determination of putative biological functions of the inactivated proteins. Some of the gene disruption methods also allow analysis of protein localization [351], which can aid functional annotation. When specifically screening for extracellular enzymes, secretion can also be predicted on the basis of sequence information [352] or transcript analysis [353]. Alternatively, the use of yeast-based signal sequence traps allows selection of secreted proteins from both eukaryotes and prokaryotes without prior sequence information [354]. Large-scale analysis of protein interactions by genetic 2-hybrid or biochemical/mass spectrometric approaches has also been used to assign function [355]. In addition, computational methods have proven successful in predicting functional interaction between proteins [357].

So far, however, genome-wide transcript analysis has emerged as most used tool for functional genomics. Based on the assumption that proteins with similar functions show similar regulation, transcript data can be used to functionally classify genes [356], [358], [359]. Microarrays of oligonucleotides or entire genes representing the complete genome can be hybridized with differentially labelled cDNAs obtained from separate cells or cell states. Comparison of transcript profiles indicates regulation of gene expression as a result of changes in the cell's conditions. Alternatively, differential expression of proteins can also be followed directly at the level of protein — albeit still at lower throughput — instead of indirect assessment

via the analysis of transcription [360]. Co-regulation of genes (or proteins) can then be used to identify genes that are relevant to a particular cellular process. For example, global transcript analysis in *Thermotoga maritima* is used to identify genes involved in the biodegradation of simple and complex plant polymers with potential as renewable energy sources, such as xylan and cellulose [361]. Designing a whole-genome DNA microarray for a fully sequenced microbe is conceptually straightforward [352]. Arraying multiple DNA arrays simultaneously can further increase throughput of expression analysis. For example, expression levels of more than 6000 human genes in 49 different cell types were recently detected in a single hybridization experiment [363]. Many other applications exist for the use of DNA microarrays in addition to transcript profiling [359].

4.1.6. Proteomic Screening

The above-mentioned functional genomics approaches are all clearly very valuable, but they still infer protein function indirectly. Direct assays for function require high-throughput expression of the identified genes, followed by functional analysis of purified proteins. This approach introduces new challenges to protein expression, including the need for high-throughput cloning and purification [364]. Many new technologies that facilitate such large-scale approaches are not limited to the full complement of sequenced genomes, the proteome, but can be adapted for the functional analysis of large numbers of recombinant proteins, for instance, those encoded by cDNA or environmental libraries.

Although any gene can be engineered to alter specific restriction sites and facilitate cloning into a suitable vector, this process cannot efficiently be performed when dealing with large sets of genes. To circumvent this, several recombination-mediated cloning strategies have been developed that allow flexible cloning into many different vectors [365-367]. High-throughput protein purification requires fusion with specific affinity tags that facilitate purification, immuno-localization, and/or immuno-precipitation [368], [369]. For example, genome-wide fusion to different tags has allowed parallel purification and characterization of thousands of different proteins. Protein fusions have also been used to improve secretion and solubility of small or low-solubility proteins. Although addition of tags might affect protein function, they strongly facilitate detection and purification, and can allow cell surface display or immobilization on beads or any other support [370-372].

Some exciting examples of proteomic screening were reported in the late 1990s and early 2000s. Expressed more than 6000 yeast genes fused to glutathione S-transferase (GST) were expressed [370]. Pools of purified fusion proteins were assayed for different enzymatic activities, and after deconvolution specified activities could be assigned to orphan genes. In a related approach nearly all protein kinases from baker's yeast were arrayed in microwells and simultaneously analysed by using 17 different substrates [373]. The same authors also expressed most yeast genes with a 6xHIS tag, which allowed binding of the fusion proteins to nickel-coated slides. The purified proteins were printed on these slides and screened for their ability to interact with proteins and phospholipids. Probing the proteome chips yielded many new functional interactions [371]. In two independent studies fusion proteins were also used to purify and characterize multiprotein complexes on an unprecedented scale [372], [374]. In a related study it was shown that an affinity purified TAP-tagged multiprotein complex retained its activity [375].

Many ideas to construct protein chips are being pursued [376] but from an enzyme screening perspective attention should focus on methods that are most likely to retain enzymatic activity. In an interesting alternative [377], instead of printing proteins, an expression library is printed and overlayed with competent cells, resulting in localized expression by transformants. The cell clusters can then be screened for clone-dependent properties. Cell surface display of protein libraries has been used to select novel or improved binders but can also be used to screen for enzymatic activity [378]. For example, mutants with improved catalytic activity have been identified by surface display of cellulase [379] and subtiligase [380]. Combined display of a quenched fluorescent substrate and a library of protease variants has been used to screen for novel substrate specificity [305]. Such approaches should also make it feasible to screen expression libraries of natural diversity.

4.2. Protein Engineering

4.2.1. Introduction

Protein engineering employs a combination of tool sets that allow any amino acid in the amino acid sequence of a protein to be replaced by one of the other 19 naturally occurring amino acids of proteins in order to change their properties. The genetic code can also be expanded by the introduction of nonnatural

amino acids into a protein [381-383]. These changes can be either directed to one position or randomly spread along the whole primary sequence.

The establishment of protein engineering as a new technology has been enabled by the advent of recombinant DNA technology, accompanied by the continuous improvement of 3D structure determination by X-ray crystallography and NMR spectroscopy.

Until the 1980s the possibilities for changing an enzyme were limited to chemical modifications, which are restricted to the reactive amino acid side chains and are neither regio- nor site-specific.

Recombinant DNA technology has revolutionized protein modification in a number of ways. It is now not only possible to replace one particular amino acid by one of the nineteen others, but these changes are also permanent. New material of the modified protein of the same quality is available simply by repeated fermentation of the production organism, followed by purification. In addition, enzymes produced in recombinant systems are available in larger quantities and higher purity. This in turn facilitates the determination of protein 3D structures and thus increases the knowledge base for further protein-engineering experiments.

Both technologies for protein structure determination, X-ray crystallography and NMR spectroscopy, have benefited from the availability of larger quantities of pure proteins, but without the simultaneous development of the physical methods the huge amount of structural data would not be available today (see Chap. Introduction). The quality of X-ray data has been improved by hardware developments of the traditional X-ray beam sources and, in particular, by the availability of coherent X-ray beams generated by synchroton radiation, which allow the resolution of crystallographic data to be brought down to down to even less than 1 Å (Fig. 22). At this level hydrogen atoms and hydrogen bonds in protein 3D structures can be directly observed [384], [385].

Figure 22. Information content of electron-density maps at different resolutions. The figure compares information available at 1.8 Å (left) with 0.78 Å (atomic resolution, right). Both maps were calculated from the same refined data set and phases derived from a refined model at 0.78 Å resolution. In both maps a standard $2F_o–F_c$ electron density was contoured at σ (blue) and 4 σ (magenta). At 0.78 Å, the 4 σ contour delineates individual atoms, and the relative dimensions indicate whether the atom is carbon, nitrogen, or oxygen having 6, 7, or 8 electrons, respectively. Contoring at 4 σ in the 1.8 Å plot does not convey this information. In the 0.78 Å map positive difference electron density (yellow) is observed for hydrogen electrons, which will be valence electrons participating in covalent bonds. As such, the positive electron density will not be centered about the hydrogen atom nucleus but rather about the covalent bond.
[Full View]

At ultra-high resolution of 0.54 Å it is even possible to study the valence electron density of proteins [386].

NMR spectroscopy has gained from the development of better magnets that allow better separation of signals and finer determination of the chemical shifts of the atoms. NMR spectroscopy is also influenced by the general developments in biotechnology that allow the effective production of the necessary ^{13}C- and/or ^{15}N-labeled proteins.

Both structure determination methods, however, were most influenced in the 1980s by the sudden availability of continuously increasing computational power. Since protein X-ray crystallography and NMR spectroscopy are indirect methods, they heavily depend upon computational power to process the data, and they require visual inspection of the results on high-end graphical computers.

The graphical computer systems paved the way for the establishment of the important knowledge base for protein engineering, the establishment of the structure-function relationship. Until then it was only possible to study the events around enzymatic catalysis by interpretation of the kinetic data under different conditions, but with the availability of structural data and cheaper graphics computers for visualization, it became possible to rationalize the observation at atomic detail by combining experimental and structural data. A very good example for this is the structural explanation for the reduction in the catalytic activity of

subtilisin due to oxidation. BOTT *et al.* [387] determined the structure of the oxidized form of subtilisin (EC 3.4.21.62) from *Bacillus amyloliquefaciens* and compared it to the nonoxidized native form (Fig. 23). In the oxidized form, the oxygen atom of the oxidized methionine 222 projects into the oxyanion hole. Thus, the substrate carbonyl atom will not bind in an identical manner as in the native enzyme. This may not only affect the relative binding energy of the substrate K_m, but the catalytic rate as well, since the oxyanion hole has been shown to be critical for catalysis. Substitution of Asn 155, for example, has been shown to reduce catalytic activity as measured by k_{cat} by 100 – 1000-fold [388].

Figure 23. Comparison of the structure of native subtilisin (blue) with the structure of the enzyme with peroxide-oxidized met 222.
[Full View]

Besides structural knowledge, the generation of mutants is a major aspect of protein-engineering experiments. In older days, the majority of mutational experiments were performed by so-called cassette mutagenesis [389], [390], a technique with which all nineteen possible natural amino acids could be substituted at a given site. From these studies variants having altered substrate specificity were found that displayed increased specificity by as much as a 1000-fold by introduction of a single mutation. Moreover, the p*K* values of catalytic residues could be modified and the pH rate profiles could be tailored to the desired performance pattern. This technique allowed the generation of site-directed mutations and of small random mutagenesis banks in defined regions of the molecules. Using this technique, numerous sites near critical subsites were determined and evaluated in subtilisin. Three amino acid changes were sufficient to interchange specificities between related subtilisins [391], while in trypsin numerous changes in addition to the position 189 side chains were needed to interchange trypsin and chymotrypsin specificities [392].

These efforts are indicative of another recurring theme in modern protein engineering, namely, the exploitation of natural diversity for guidance in selecting sites and substitutions. Natural diversity is the result of millions of years of adaptation to various extremes of conditions such as temperature, pH, and substrates. Within a certain class of enzyme the overall tertiary folding pattern is often highly conserved, and thus it is possible to associate changes that can often be introduced at particular positions and associate specific substitutions with particular alterations in performance profiles and substrate specificities. The theme of exploiting natural diversity reappears in most commonly used techniques, either for rational selection of sites and substitutions or by recombination as a means of extending diversity.

Mutagenesis Techniques. After the recognition that recombinant DNA technology could be used to modify the sequence and thereby the function of an enzyme by altering the DNA sequence encoding for the protein, the next advancement came with the advent of cassette mutagenesis [389]. Complete sampling of all natural amino acid substitutions became realizable. With this tool, the full repertoire of diversity was now available for molecular evolution, at least one site at a time.

Around the same time, the idea of alanine scanning was introduced. In this model, many sites could be examined by replacement of existing amino acid residues with alanine. In this case, the diversity looks to identify sites that may play an important role for functioning of the enzyme. In this approach potential sites are screened that can later be explored by structural analysis and/or diversity generation.

The discovery of error-prone polymerase chain reaction (PCR) was the first revolution in enzyme-variant generation. In fact, PCR allows both the production of site-directed protein variants and the generation of random variant libraries over the whole gene or defined parts of it. Mutation frequency of the error-prone PCR experiments can be driven by the reaction conditions and the choice of the polymerase.

Another method for the generation of molecular diversity at the gene level is gene shuffling [393-395]. In gene shuffling experiments a set of homologous genes is pooled and cut into pieces. Finally the fragments are recombined randomly in a subsequent PCR. As a result an enzyme variant library is obtained that allows the combinations of all natural variations that were distributed across the genes in the input set to be

explored. The variations not only allow variations of individual amino acids to be tested, but also the effect of amino acid insertions or deletions among the different proteins.

The ability to identify the right variants for a given purpose determines the success of a protein-engineering experiment. A site-directed variant is of course easy to characterize, but the screening of a random library requires excellent knowledge about the assay that is used for screening.

Phage display of proteins has become an important tool for screening and selection of proteins. In a phage-display approach, the gene which encodes for the protein to be engineered is linked to one of the genes which encode for the phage's surface proteins. As a consequence the protein is expressed at the N- or C-terminus of one of the surface proteins. Since it is on the surface, the displayed protein can be selected for binding to a certain target. Phage display allows selection from more than 10^9 variants for binding in a single experiment. In addition the selected protein is always isolated in combination with the gene that codes for it. The gene can be multiplied by infection of a host organism with the phage, followed by either sequencing or a subsequent mutagenesis/selection cycle. Phage display has now been proven to be a good tool for selection of proteins that bind selectively to a target molecule.

Although active enzymes have been expressed on phages, phage display is not a suitable technique to change the catalytic properties of enzymes. Because the binding to a transition state analogue, which can be used for a selective binding screen, does not correlate well with improved catalysis [396], [397], it is necessary to design special capturing systems for the detection of phage-displayed enzymes with high catalytic activity [398].

For the improvement of an enzyme for technical application it is of outmost importance that the selective activity assay closely resembles the final application. Several examples have clearly demonstrated that activity assays with artificial substrates show no correlation with performance in real-world applications. This was shown by correlating wash performance of a protease with the enzyme's activity on casein [399]. The directed-evolution experiment for the improvement of the activity of galactose oxidase (EC 1.1.3.9) revealed a reasonable correlation between the activity of the different galactose oxidase variants on the model substrate methylgalactose and their performance on the technical substrate guar. Ironically the best performer in the technical application had to be excluded from the dataset to obtain the good correlation coefficient of r^2=0.92 (with the best performer included the correlation coefficient was r^2=0.72) [400].

It must be clear that none of the protein engineering tools is able to improve enzymes alone. The strength of protein-engineering projects lies in the combination of structural/functional knowledge with the right molecular biology approach for the generation of variants.

Finally, the importance of screening technology has grown during the last few years. Mainly, automation in combination with miniaturization of assays down to microscopic scales has lead to a shift from pure site-directed mutations to regio-directed random mutagenesis experiments followed by intensive variant library screening.

The most comprehensive use of protein engineering is known under the names directed evolution, molecular evolution, and molecular breeding. Common to these approaches is the iterative follow up of randomization and selection steps. Directed evolution mimics the natural evolutionary process in the laboratory. It can be very successful, because the laboratory allows a nonnatural selective pressure to be applied to direct the successive improvement of a particular enzyme to improve its performance in a technical environment. Directed evolution proved to be very successful. Often three or fewer iterative cycles of randomization and selection for a desired property can achieve enormous improvements. This success can mainly be explained by the fact that the directive influences of natural evolution do not force a molecule to perform well in, e.g., a laundry washing machine. In addition, the researcher can introduce a much higher mutation frequency than occurs in Nature.

4.2.2. Application of Protein Engineering in Academia and Industry

Both the academic scientific community and industrial scientists embraced the new protein engineering technologies when they became available in the second half of the 1980s. In academia, protein engineering is used extensively for elucidating intrinsic protein and enzyme properties such as stability, catalytic

mechanism, and activity under different conditions. Industrial scientists focus on engineering for improved performance of enzymes in industrial applications.

Deciphering the Catalytic Mechanism. Protein engineering can be used to identify amino acids which participate in the catalytic mechanism, before or even after the availability of 3D structural information. The most comprehensive studies on enzyme mechanisms by protein engineering were performed on tyrosyl-tRNA synthetase starting in the 1980s [401]. The complete investigation has been summarized elsewhere [402].

Protein engineering has also been used for the identification of the active sites in proteins, for example, in lipases. The principle nucleophile in hormone-sensitive lipase was identified by sequence analysis of the characteristic GXSXG segment of the α/ β-hydrolase fold and subsequent replacement of serine 423, by several other amino acids. Since all variants had no activity at all, the authors could conclude that serine 423 is indeed the active site serine of this lipase [403]. Other groups identified in similar experiments the whole catalytic triad of different lipases [404], [405]. The investigations of MARTINELLE, HOLMQUIST *et al.* [406], [407] expand this concept by investigating the role of amino acids in the proximity of the active site of *Humicola lanuginosa* lipase in substrate specificity. They combined mutagenesis results of interesting mutants with careful kinetic investigations of the variants under different conditions.

Stability of Enzymes. Fundamental Research. The intrinsic stability of proteins and the influence of single amino acids on the stability of proteins have been investigated with protein-engineering. Since the effect of exchanging an amino acid on protein structure depends on its position in the protein structure, it is necessary to use the right model system and to plan the mutation on the basis of the 3D structure of that protein.

One route to a more stable protein is the introduction of disulfide bonds by site-directed mutagenesis. In subtilisin, an enzyme having no cysteine residues, the introduction of cysteine for serine or alanine at positions 22 and 87 or 24 and 87 resulted in the formation of disulfide bridges [408] but yielded enzymes with little or no improvement in overall stability. CLARKE *et al.* showed in a study on barnase that engineered disulfide bonds can stabilize and destabilize proteins. The most stabilizing disulfide bridge does not change the overall structure of the molecule and leads to local stabilization according to hydrogen-exchange experiments. The destabilizing disulfide bridge induced considerable structural changes, including the displacement of a loop in the vicinity of the new disulfide bond [409], [410].

The influence of single amino acid replacements has been studied in detail with several model proteins. The studies clearly show that the influence of an amino acid on helix stability depends on its intrahelical position, the position of the helix in the globular protein structure, and the solvent accessibility of the mutation site [411-413].

The complexity of interaction between stabilizing and destabilizing mutations during evolution has been demonstrated in a comparative mutagenesis study with barnase and binase. Both are RNAses with 85 % sequence identity. Only 17 amino acids, scattered over the whole sequence, differ in these proteins, which have the same 3D structure but differ in stability. One-by-one replacement and combinations of the single mutations showed that each mutation has an effect on stability and that the effects are additive. However, a combination of only six of these mutations created a protein more stable than either of the parent molecules without affecting the activity [414]. This study shows that a simple comparison of sequences and 3D structures of enzymes from mesophilic and thermophilic organisms will not lead to the identification of the stabilizing amino acid changes, because nature balances several effects during evolution to obtain a set of enzymes which is good enough for its purpose.

Industrial Application. Enzymes have been successfully incorporated into industrial starch processing. In the first stage α-amylase is used to break down starch into short oligosaccharides. In the commercial process the enzyme must survive passage through a steam jet at 105 °C, which is necessary to explode the starch granule, and function at 90 °C for 1 – 2 h. With the natural amylase of choice, *B. licheniformis* α-amylase (BLA), the pH must be adjusted to 6 and then readjusted in subsequent stages. An engineered α-amylase that would operate at lower pH would save considerable time and money by eliminating the need for pH adjustment. Analysis of BLA as a function of pH indicated that stability of the enzyme was reduced at lower pH. Initially, random mutagenesis and screening was performed in the absence of a reliable model of its three-dimensional structure, and several variants were identified [415]. Once a structure became available it

was noticed that variants represented substitutions found to exist between related α-amylases. Surprisingly, the related α-amylases had lower overall stability than BLA. By using the three-dimensional structure as a guide it was realized that all of the variant substitutions were located on the surface and filled a cavity present on the surface of BLA. An additional five residues were identified, and each individually increased the stability of the enzyme and could be combined with a cumulative increase in stability by a factor of 23.

Subtilisin operates in an environment quite different from its natural milieu. As a detergent additive, subtilisin must perform at highly alkaline pH, high surfactant concentration, and high temperature. It must operate on a wide variety of proteinaceous soils and may encounter other agents such as oxidants like hydrogen peroxide, added as a bleaching agent. Thus the enzyme was engineered to be more active and stable under these conditions. One of the most beneficial results has been mutations from which susceptibility to oxidants found in commercial bleaching agents has been eliminated. This was primarily achieved by replacing a bleach-sensitive methionine residue [416].

Investigations on Protein Folding. The application of protein engineering for the dissection of protein folding pathways has been reviewed [417]. The number of different experimental techniques that have been used for this purpose clearly emphasizes the interdisciplinary nature of protein engineering.

Changing the Substrate Specifity of Enzymes. The use of enzymes as biocatalysts for chemical reactions has recently regained interest (see Enzymes in Organic Synthesis). Several protein-engineering projects have been successfully performed. They mainly applied different directed-evolution approaches to demonstrate their capabilities for the development and improvement of new biocatalysts.

The activity of subtilisin E in aqueous DMF was improved by protein engineering [418], [419]. Subtilisins have only low activity and reduced stability in DMF. The authors were able to enhance the stability in 40 % DMF more than twofold. But even more important is the activity enhancement that was achieved by subsequent evolution cycles. The final molecule showed a 471-fold activity improvement in 60 % DMF on a test substrate compared to the wild-type molecule.

The ability to change the substrate range and selectivity by protein engineering methods has been demonstrated by several authors. ZHANG *et al.* [420] used DNA shuffling to modify the substrate specificity of β-galactosidase (EC 3.2.1.23). Whereas the wild-type molecule showed no activity on test substrates with fucose moieties, the final enzyme was active against these substrates. The activity against galactose substrates dropped significantly.

The success of engineering of enantioselective enzymes finally demonstrates that protein-engineering technologies nowadays can even address the subtlest problems in chemical synthesis. In several studies on various enzymes it has been demonstrated that it is possible to protein-engineer enzymes to obtain improved enantioselectivity, mainly for hydrolysis reactions [421-423].

4.2.3. Outlook

There are similarities between natural and directed evolution, the difference being largely in the management of diversity. Protein engineering has always been directed evolution where screening and diversity management intervene in place of natural selection. Even now knowledge of the three-dimensional structure and its relation to function is often pivotal in locating critical sites and regions for focused diversity and recruitment. DNA shuffling techniques again use screening strategies to combine features between natural selected genes in an effort to recombine or recruit the desirable features in a family of enzymes.

Now with the knowledge of whole genomes and the expected comparison of the genomes of closely related species, it may be possible to perform in silico shuffling and perhaps understand inherent preferences on individual molecular evolution imposed by the organisms' metabolome — the ensemble of molecular functions necessary for the maintenance of metabolism and reproduction in the whole organism. Another element of in silico directed evolution is the requirement to be able to predict the three-dimensional structure and with this further be able to recognize the catalytic potentials and even to deduce the probable physiological role of that molecule within the metabolome.

5. Industrial Enzymes

5.1. Enzymes in Food Applications

5.1.1. Enzymes in Baking

5.1.1.1. Introduction

Bread and baked products are among the main nutritional sources today. Over 600 × 10^6 t of wheat are grown in the world each year, making it the single most important crop [424]. Europeans are estimated to obtain approximately half their required carbohydrates and about one-third of their protein from bread [425].

Throughout the history of bread making, enzymes have always played an important role. Even the ancient Egyptians made use of enzymes present endogenously in the flour, although they may not have been aware of the effect. However, not until the 20th century were enzymes used as flour improvers [426]. The first application of enzymes in baked goods was supplementation of α-amylase by addition of malt to correct the concentration of endogenous α-amylase in the flour. Later malt was substituted by microbial α-amylases having a more suitable thermostability for baking. This was the first enzyme industrially produced as a tool to compensate for variations in natural flour. Today, a whole range of enzymes is available for end users of flour. These make it possible to correct suboptimal concentrations of endogenous flour enzymes. Furthermore, these biological catalysts are able to produce value-adding ingredients in situ from compounds present in the flour, and thus it is possible to upgrade lower grades of flour.

In many cases the beneficial effects of using enzymes in the baking industry are also obtainable by using chemical agents such as sodium metabisulfite, cystein, azodicarbonamide (ADA), potassium bromate, etc. However, the food market today shows a clear trend towards more “green” products, and this has clearly favored the use of the biological catalysts enzymes.

Baking enzymes are summarized in Table 9.

Table 9. E.C. numbers; reactions; and recommended, systematic, and other names of baking enzymes according to IUBMB (http://www.chem.qmul.ac.uk/iubmb/)

Recommended name	E.C. number	Systematic name	Reaction	Other name(s)
α-Amylase	E.C. 3.2.1.1	1,4- α-D-glucan glucanohydrolase	endohydrolysis of 1,4- α-D-glucosidic linkages in polysaccharides containing three or more 1,4- α-linked D-glucose units	glycogenase; α amylas amylase; endoamylase amylase A
Glucan 1,4- α-maltohydrolase	E.C. 3.2.1.133	1,4- α-D-glucan α-maltohydrolase	hydrolysis of (1 → 4)- α-D-glucosidic linkages in polysaccharides so as to remove successive α-maltose residues from the nonreducing ends of the chains	maltogenic α-amylase
Endo-1,4- β-xylanase	E.C. 3.2.1.8	1,4- β-D-xylan xylanohydrolase	Endohydrolysis of 1,4- β-D-xylosidic linkages in xylans	endo-1,4-xylanase; xyl 1,4-xylanase; endo- β- xylanase; endo-1,4- β- xylanase; 1,4- β-xylan xylanohydrolase; β-xy 1,4-xylan xylanohydro D-xylanase
Glucose oxidase	E.C. 1.1.3.4	β-D-glucose:oxygen 1-oxidoreductase	β-D-glucose + O_2 D-glucono-1,5-lactone + H_2O_2	glucose oxyhydrase; corylophyline; penatin aerodehydrogenase; m β-D-glucose oxidase; D oxidase; D-glucose-1-c β-D-glucose:quinone oxidoreductase; glucos oxyhydrase; deoxin-1;
Hexose oxidase	E.C. 1.1.3.5	D-hexose:oxygen 1-oxidoreductase	β-D-glucose + O_2 → D-glucono-1,5-lactone + H_2O_2	
Galactose oxidase	E.C. 1.1.3.9	D-galactose:oxygen 6-oxidoreductase	D-galactose + O_2 → D-galacto-hexodialdose + H_2O_2	D-galactose oxidase; β- galactose oxidase
Pyranose oxidase	E.C. 1.1.3.10	pyranose:oxygen 2-oxidoreductase	D-glucose + O_2 → 2-dehydro-D-glucose + H_2O_2	glucose 2-oxidase; pyr oxidase
Thiol oxidase	E.C. 1.8.3.2	thiol:oxygen oxidoreductase	4 R′C(R)SH + O_2 → 2 R′C(R)S-S(R)CR′ + 2 H_2O	sulfhydryl oxidase
L-Amino-acid oxidase	E.C. 1.4.3.2	L-amino-acid:oxygen oxidoreductase (deaminating)	L-amino acid + H_2O + O_2 → a 2-oxo acid + NH_3 + H_2O_2	ophio-amino-acid oxid
Lipoxygenase	E.C. 1.13.11.12	linoleate:oxygen 13-oxidoreductase	linoleate + O_2 → (9*Z*,11*E*)-(13*S*)-13-hydroperoxyoctadeca-9,11-dienoate	lipoxidase; carotene ox lipoperoxidase; fat oxi lipoxydase; lionoleate: oxidoreductase
Peroxidase	E.C. 1.11.1.7	donor:hydrogen-peroxide oxidoreductase	donor + H_2O_2 → oxidized donor + 2 H_2O	myeloperoxidase; lactoperoxidase; verdoperoxidase; guai peroxidase; thiocyanat peroxidase; eosinophil peroxidase; Japanese r peroxidase; horseradis peroxidase (HRP); ext

				peroxidase (MPO); chl peroxidase; heme pero MPO; oxyperoxidase; protoheme peroxidase; pyrocatechol peroxidas scopoletin peroxidase
Catechol oxidase	E.C. 1.10.3.1	1,2-benzenediol:oxygen oxidoreductase	2 catechol + O_2 → 2 1,2-benzoquinone + 2 H_2O	diphenol oxidase; *o*-diphenolase; phenolase polyphenol oxidase; ty pyrocatechol oxidase; oxidase; catecholase; *o* diphenol:oxygen oxidoreductase; *o*-diph oxidoreductase
Laccase	E.C. 1.10.3.2	benzenediol:oxygen oxidoreductase	4 benzenediol + O_2 → 4 benzosemiquinone + 2 H_2O	urishiol oxidase; urush oxidase; *p*-diphenol ox
Monophenol monooxygenase	E.C. 1.14.18.1	monophenol,L-dopa:oxygen oxidoreductase	L-tyrosine + L-dopa + O_2 → L-dopa + dopaquinone + H_2O	tyrosinase; phenolase; monophenol oxidase; catechol oxidase; polyphenolase; pyroca oxidase; dopa oxidase; chlorogenic oxidase; catecholase; polyphen oxidase; monophenola diphenol oxidase; chlo acid oxidase; diphenol o-diphenolase; tyrosine oxidase; o-diphenol:ox oxidoreductase; polyar oxidase; monophenol monooxidase; o-diphe oxidoreductase; monop dihydroxyphenylalanin oxidoreductase; *N*-acet hydroxytryptophan oxi monophenol, dihydrox phenylalanine oxygen oxidoreductase; *o*-diph oxidoreductase; pheno
Triacylglycerol lipase	E.C. 3.1.1.3	triacylglycerol acylhydrolase	triacylglycerol + H_2O → diacylglycerol + a carboxylate	lipase; triglyceride lipa tributyrase; butyrinase; ester hydrolase; tributy Tween hydrolase; stea triacylglycerol lipase; triacetinase; tributyrin Tweenase; amno *N*-AP 1969-4-9; Meito MY 3 Tweenesterase; GA 56 capalase L; triglyceride hydrolase; triolein hyd tween-hydrolyzing est amano CE; cacordase; triglyceridase; triacylg ester hydrolase; amano amano AP; PPL; glyce hydrolase; GEH; meito OF lipase; hepatic lipa

5.1.1.2. Amylases

Amylases for Flour Standardization. The most widely used enzyme in bread baking in terms of amount dosed and value is so-called fungal α-amylase or Taka-amylase from *Aspergillus oryzae* (E.C. 3.2.1.1). This is supplemented to sound flours to optimize their α-amylase activity with regard to final volume and crumb structure of the baked product. The primary effect of amylase supplementation was previously believed to be securing adequate gassing power by degradation of damaged starch granules in the dough, which facilitates maltose production by endogenous β-amylase. The resulting maltose can serve as fermentable sugar for yeast fermentation [427]. This mechanism may be important in some very lean dough systems without added sugars, but generally the primary effect is reduction of dough viscosity during initial starch gelatinization [428], which provides a prolonged oven spring leading to an increased volume and a more homogenous crumb structure.

Taka-amylase is named after Takamine, who in 1894 obtained US patent 525 823 on the use of mold fungi for production of amylase. The use of fungal amylase in bread baking was patented in 1928 [429] but first approved in 1955 for use in bread baking in the USA. The advantage of Taka-amylase is a very low protease

side activity and an adequate thermostability, so that inactivation of the enzyme occurs after initial starch gelatinization (70 – 80 °C). The most common alternatives — malt amylases from barley or wheat malt — have higher protease side activities and higher thermostability, and this makes them more prone to negative side effects when overdosed [430].

Antistaling Amylases. The second important goal for use of amylases in baking is antistaling, i.e., improving the fresh keeping of baked goods. Staling is a highly complex phenomenon [431-434], but it is generally accepted that retrogradation of amylopectin is the main contributor to bread staling. The original model for the role of starch was developed by SCHOCH in 1965 [431]. Upon cooling in the first hours after baking the initial crumb structure is set by amylose gelation, which creates a network in which the gelatinized starch granules are embedded. Recrystallization of amylopectin side chains leads to rigidification of the starch granules and to an overall strengthening of the crumb structure, measured as an increase in crumb firmness.

Different types of amylases used for antistaling provide different functionalities. First, a limited effect of fungal α-amylase is caused indirectly by volume increase. Secondly, endo-amylases weaken the amylose network, leading to reduced crumb firmness immediately after baking and during storage. This effect is more pronounced when endo-amylases with high thermostability are used. An example of the most effective type is the *B. amyloliquefaciens* α-amylase, which has been used in the USA since the 1950s [435]. This amylase survives baking and is probably active during cooling of the bread and during storage [436]. Consequently, only a very narrow window of optimal dosage exists, and even moderate overdosing can lead to keyholing of the bread and a gummy crumb structure with strongly reduced elasticity (resilience). As an alternative, intermediately thermostable amylases have been developed. They have lower risks of overdosing, but are also limited in their antistaling effects [436].

Compared to endo-amylases, exo-amylases such as the so-called maltogenic amylase (E.C. 3.2.1.133) offer clear improvements for antistaling applications. By shortening the amylopectin side chains and releasing maltooligosaccharides, they efficiently reduce the rate of amylopectin retrogradation without disadvantageous side effects caused by weakening of the amylose network [437]. In a model system the shortening of amylopectin side chains has been shown to reduce retrogradation substantially [438].

5.1.1.3. Xylanases

Xylanases (E.C. 3.2.1.8, β-1,4-D-xylan xylanohydrolase), traditionally named pentosanases or hemicellulases, catalyze the endo-hydrolysis of β-1,4-D-xylosidic linkages in xylans. In dough, xylanases reduce problems associated with variations in flour quality, improve dough handling and dough stability, and give improved crumb structure and bread volume [439], [440].

The target substrates in cereals used for baking are arabinoxylan (AX; Fig. 31), one of the major nonstarch polysaccharides in cereals, making up 60-70 % of wheat cell walls [441] and 2 – 3 % of cereal flour [440].

Figure 31. Model structure of arabinoxylan
[Full View]

Traditionally, the arabinoxylans have been divided into two fractions, a not extractable with water arabinoxylan fraction (WU-AX) and a water-extractable arabinoxylan fraction (WE-AX). Why some AX are water-extractable and others are not has been the topic of many studies. Early hypotheses explaining the differences were based on structure analysis of the two fractions, which showed a difference in the degree of substitution [442]. However, recent literature points more in the direction of both fractions having a similar degree of substitution [443], but the molecular weights of the two AX fractions differ, with WU-AX having the higher molecular weight. Furthermore, the concentrations of diferulates in the two fractions differ, and this may at least partly explain the difference in molecular weight and extractability of the two AX populations. The WU-AX has a much higher concentration of diferulates than the WE-AX [444]; this higher concentration of cross-linking between AX molecules will increase the molecular weight and probably make part of the AX water-unextractable.

Some of the best known characteristics of cereal AX are the water-holding capacity of WU-AX and the

ability of AXs to produce viscosity. GIRHAMMER [445] showed that WU-AX could absorb water corresponding to 10 times its own weight, and IZYDORCZYK and BILIADERIS [446] showed that AX has a very high intrinsic viscosity. These characteristics are probably the main factors determining the functionality of xylanases in the baking industry. In some baked products these phenomena are beneficial, but in others they are not.

Depending on the nature of the baked product, the flour AX may influence, in different ways, dough processing, dough characteristics, and the quality of the final product. This calls for the use of different, specific xylanases. In proofed and raised bread types, literature characterizes the WU-AX as detrimental for gluten strength and hence also for the stability of the dough [447], [448]. By influencing the dough stability, WU-AX also influences dough machinability and the quality of the final bread. Without xylanases the final products will have a more open crumb, and the volume will be smaller compared to dough in which the WU-AX fraction has been modified by a xylanase. Solubilizing the WU-AX into high molecular weight solubilized arabinoxylan (S-AX) by using a specific xylanase opens the possibility of converting WU-AX into a functional polymer. The high molecular weight S-AX will act as a hydrocolloid and increase the viscosity in the dough, giving a more stable dough system. The use of WU-AX-specific xylanases in such baked products will typically improve the dough stability, dough machinability, and improve crumb structure and volume (10 – 30 %) of the final product [439].

In dry cereal products such as crispbread, crackers, etc., AX influences the dough or batter characteristics through its viscosity-enhancing properties [449]. Furthermore, AX influences the evaporation of water during baking of these products, due to its high water-binding capacity, which prevents even and fast evaporation of water from the product. This may result in longer baking time, checking, and darker products. In contrast to the specificity of the xylanase mentioned above, the xylanase used in dry cereal products should be specific for WE-AX and S-AX, and thus decrease dough resistance and dough liquid viscosity.

5.1.1.4. Oxidoreductases

Oxidative enzymes have a beneficial effect on dough development and dough quality. Dough quality influences other quality parameters such as volume, texture, and crumb structure of the baked product [450]. During dough mixing and molding, disulfide linkages are formed and broken between gluten proteins. When this reaction takes place optimally, it leads to a good dough development, that is, a strong gluten network is formed. Chemical oxidants such as ascorbic acid and bromate are used in breadmaking worldwide to support and promote the formation of disulfide linkages. Today consumers in the Western world prefer food without added chemical ingredients. Due to regulatory problems with bromate in the USA and the E.C. countries, the wish to replace bromate exists. Hence, substitution with oxidative enzymes is a desirable alternative.

Glucose oxidase (E.C. 1.1.3.4) is usually obtained from *Aspergillus niger*. Glucose oxidase catalyzes the oxidation of glucose with consumption of oxygen to give gluconolactone and hydrogen peroxide. The generated hydrogen peroxide reacts with free thiol groups in the gluten with formation of disulfide linkages, which give increased gluten strength [451]. Glucose oxidase is known to give a dry and nonsticky dough, the latter characteristic being very useful in combination with xylanases, which may cause some stickiness when used alone [452].

Hexose oxidase (E.C. 1.1.3.5) is an enzyme originating from carrageenan seaweed, *Chondrus crispus*. This enzyme has broad substrate specificity, being able to oxidize glucose, galactose, maltose, etc. [453]. The enzyme oxidizes the endogenous substrates of the flour, mainly glucose and maltose, to the corresponding lactones with consumption of oxygen and formation of hydrogen peroxide. The hydrogen peroxide formed then oxidizes the thiol groups in the gluten proteins with formation of disulfide bonds [453].

Lipoxygenase (E.C. 1.13.11.12) enters bread production through the use of soybean flour or bean flour (France) that has not been heat-treated, i.e., is still enzymatically active. It improves the whitening of the breadcrumb. Lipoxygenase catalyses the oxidation of unsaturated fatty acids containing *cis*-*cis*-1,4-pentadiene groups. The resulting fatty acid hydroperoxide can react with carotenoids in the dough. According to CASEY [454] the molecular basis of bread improvement through the action of lipoxygenase is likely to involve the formation of intermolecular disulfide bridges between the high molecular weight gluten proteins [454].

Sulfhydryl oxidase (E.C. 1.8.3.2), isolated from *A. niger*, catalyzes the oxidation of free sulfhydryl groups to

disulfide groups in a variety of reduced thiol systems. A discussion continues as to whether sulfhydryl oxidase has only limited affinity for SH groups in high molecular weight substrates such as gluten [450]. SZALKUCKI wrote: “further testing is necessary to demonstrate the commercial utility of sulfhydryl oxidase in baking” [455].

Peroxidase (E.C. 1.11.1.7, horseradish peroxidase) is the general name for a group of enzymes with different substrate specificity. All peroxidases act on hydrogen peroxide as electron acceptor and oxidize a multitude of donor compounds [456].

During the peroxidase reaction a free radical is produced that reacts nonenzymatically with other compounds present in the dough [457]. It is well documented that certain peroxidases have a dough-improving effect [457], but different theories exist concerning the mechanism of function. The peroxidase might form diferulic acid bridges and thus lead to covalent cross-linking of arabinoxylans [458]. Coupling of arabinoxylans to proteins has also been demonstrated in model systems; this proceeds by oxidative cross-linking between ferulic acid and cysteine and/or tyrosine residues in proteins [457]. Finally, model studies also indicated the action of peroxidases in dough strengthening to be the result of protein – protein cross-linking through lysyl residues. Sulfhydryl groups may also be involved [457].

Polyphenol oxidase oxidizes diphenolic groups to quinones. Three types of enzymes are included in the group of polyphenol oxidases. Tyrosinase (monophenol monooxygenase, E.C. 1.14.18.1), diphenol oxidase or catechol oxidase (E.C. 1.10.3.1), and laccase (E.C. 1.10.3.2). Two mechanisms for the action of polyphenol oxidases in dough are postulated. One involves oxidation of ferulic acid esterified to arabinoxylan, which induces their cross-linking, and the other assumes cross-linking of gluten proteins by oxidation of tyrosyl groups or by conjugation between tyrosyl and thiol groups [459].

A number of enzymes that generate hydrogen peroxide by oxidation of various substrates with consumption of oxygen have been described as having dough-improving effects: glycerol oxidase [460], pyranose oxidase (E.C. 1.1.3.10) [461], L-amino acid oxidase (E.C. 1.4.3.2) [462], galactose oxidase (E.C. 1.1.3.9) [463].

5.1.1.5. Lipases

Lipases (E.C. 3.1.1.3) can be defined as carboxylesterases which catalyze the hydrolysis of long-chain acylglycerols to glycerol, free fatty acids, and mono- and di-glycerides. The substrate for lipases in wheat flour is the 2–3 % of endogenous wheat lipids. The composition of the free lipids (extractable with water-saturated butanol at room temperature) is shown in Figure 32.

Figure 32. Composition of total wheat flour lipids, extracted with water saturated butanol [464] [Full View]

Lipids are probably the longest known and used bread improvers, whereas the use of lipase as a bread improver is relatively new. The understanding of lipase functionality is continuously being studied, but is mostly based on knowledge of the effects of lipids in dough and baking. The desirable effects obtained by lipases are improved dough stability and better dough handling properties, and improved stability of the gas cells in dough, yielding a nice, homogenous crumb structure and increased bread volume.

Lipase modifies flour lipids or added lipids, and the beneficial effect of an added lipase is dependent on the effect of the hydrolysis products [465]. Some of these hydrolysis products are quite surface-active or more surface-active than the unmodified lipid and therefore better stabilize the gas cells in the dough. This again leads to better crumb structure, increased dough stability, and increased volume [466]. Among the potential reaction products, monoglycerides are well-known crumb softeners in baking, as they form a complex with starch and thus decrease retrogradation [452].

Phospholipases are a class of four enzymes hydrolyzing specific bonds in phospholipids (see Fig. 33): phospholipase A1 (E.C. 3.1.1.32), phospholipase A2 (E.C. 3.1.1.4), phospholipase C (E.C. 3.1.4.3), and

phospholipase D (E.C. 3.1.4.4).

Figure 33. Phospholipase specificity (modified from A. L. Lehninger Biochemistry, Worth Publishers, Inc. 1970, p. 199, fig 10-4.)
[Full View]

The release of one fatty acyl chain from phosphatidylcholine yields 1-acylglycerophosphorylcholine, more commonly known as lysolecithin, which is an excellent emulsifier with a very positive effect in baking [467].

5.1.1.6. Proteases

Proteases (E.C. 3.4.X.X) catalyze the hydrolysis of peptide bonds in proteins [468]. Depending on the protease used, this modification may lead to a minor modification that gives more extensible dough [469], [470] or to an extensive hydrolysis of the gluten structure with loss of the viscoelastic properties [470]. Apart from the impact on the physical and rheological properties of the dough, some proteases are known to influence the flavor and color of the final product as well.

As proteins are a highly heterogeneous population of molecules, due to the 20 amino from which they are composed, the population of enzymes capable of hydrolyzing proteins is also very diverse [471]. This population of enzymes is divided into two categories: the peptidases and the polypeptidases (synonymous with proteases). The peptidases are exo-acting enzymes that remove one amino acid or a peptide from the C- or N-terminus of the protein, and the proteases are endo-acting

Wheat flour is unique in its ability to form a viscoelastic gluten matrix when mixed with water [472]. This gluten matrix can retain gas in the dough, giving wheat flour its unique baking performance. The quality and quantity of protein are therefore major quality parameters for wheat flour [424], [473].

In normal raised bread products too strong a flour may prohibit a good volume, as proper expansion of the dough will not be possible. Application of a moderate specific protease (typically a fungal protease) modifies the gluten, giving a better extensibility, faster development, and thereby better structure and volume of the final product [470]. The same functionality can be obtained by using chemical reducing agents, such as L-cysteine or sodium metabisulfite (Fig. 34). However, the biological, and labeling-free enzyme solution is often preferred.

Figure 34. Gluten protein structure and modification by proteolytic hydrolysis or chemical reduction, respectively [After [425] (H. Uhlig: “Enzymes in flour processing and baking”, in: *Industrial Enzymes and their Application*. John Wiley & Sons, Inc. (1998). fig 5.36, pp 284)]
[Full View]

In cracker, biscuit, wafer, and pizza dough weaker flour having less viscoelastic properties is preferred [474]. A strong gluten network would prohibit the right shape and texture of the final product. Applying less specific proteases (typically a *Bacillus* protease) to these types of products allows the manufacturer to be more independent of flour quality. It is possible to obtain the desired dough rheological properties by using most flours in combination with protease. Again, the same solution is obtainable with chemical reducing agents, but the demand for biological and labeling-free solutions favor enzyme solutions.

Application of peptidases to bread might influence the flavor and crust color of the product [470]. The products of the peptidase, amino acids or peptides, influence the flavor. The amino acids are intermediate products in the production of aromatic components, and peptides are potential oxidants, taste enhancers, sweeteners, and bitter agents [475]. Furthermore, amino acids released from gluten proteins can react with

sugar through the Maillard reaction, thereby contributing to flavor and crust color.

5.1.1.7. Transglutaminase

Transglutaminase (protein-glutamine ϒ-glutamyltransferase, E.C. 2.3.2.13) introduces covalent cross-links in proteins by forming a bond between lysine and glutamine residues. Based on its ability to cross-link gluten proteins it can be used as a dough strengthener for bread and other baked products [476]. As further advantages reduction of the needed work input as well as increased water binding have been reported [477].

5.1.2. Enzymes in Fruit Juice Production and Fruit Processing

5.1.2.1. Introduction

The first application of enzymes in the fruit juice industry was the use of pectinases for apple juice clarification in the 1930s [478]. The fast clarification of juice after breakdown of pectin by pectinases and the decrease in juice viscosity resulted in a shorter process and greatly improved the quality of industrial apple juice. Later, pectinases were applied to depectinization of red-berry juice. The use of pectinases and amylases to degrade apple pectin and starch during the hot clarification stage prevents post-bottling haze formation, and thus concentration of the juice by a factor of six has become possible. This results in a smaller storage volume, cheaper transportation, and better concentrate stability without spoilage. Treatment of apple pulp with pectinases and hemicellulases was introduced later: by lowering the viscosity of the pulp, the press capacity and the yield were significantly improved. Depectinization of juice with pectinases with high arabanase activity improved product quality further by preventing araban haze formation after concentration of the juice. In the production of clear and stable red-berry juice or concentrate, hot maceration with enzymes ensures a higher juice yield and a better color extraction [479]. Nowadays, enzyme suppliers provide fruit juice producers with tailor-made enzyme preparations optimally blended on the basis of fruit composition for improved quality and stability of finished products, together with shorter process duration and larger plant capacity. In association with new equipment and processing technologies, industrial enzymes allow processors to add value to raw material for food and feed and to reduce waste quantity. Industrial processes are very diverse and numerous. Here the most common are described, but differences still exist depending on the company and plant.

5.1.2.2. Biochemistry of Fruit Cell Walls

The pulp of fruits and vegetables is composed of cells. They are surrounded by a cell wall, which resists internal pressure and external shock (Fig. 35). Polysaccharides constitute 90 – 100 % of the structural polymers of walls of growing plant cells, known as primary cell walls. Secondary cell walls develop from primary cell walls during cell growth. Cell wall composition depends on fruit species and evolves in dependence on agronomic and climatic conditions, fruit ripeness, the type and duration of storage of the fruit (cell growth and cell senescence). The composition of plant cell walls has been widely studied, and numerous models of the three-dimensional structure have been proposed [480], [481]. Three major independent domains are distinguished: the xyloglucan network, the pectin matrix, and the structural proteins. The cellulose – xyloglucan network is embedded in the pectin matrix. Pectin is the major structural polysaccharide component of fruit lamellas and cell walls. Three pectic polysaccharides are present in all primary cell walls: homogalacturonan and rhamnogalacturonans I and II [482] (Fig. 36). Recent models divide pectin into so-called smooth regions of unbranched homogalacturonan (60 – 90 %) and hairy regions of highly branched rhamnogalacturonan I (10 – 40 %) [484], [485]. Homogalacturonan is a homopolymer of (1→4)- α-D-galactosyluronic acid residues, capable of forming gels. Carboxyl groups of the galactosyluronic acid residues of primary cell wall homogalacturonan can be methyl-esterified at the C-6 position and acetyl-esterified at the C-2 or C-3 position. Helical chains of homogalacturonan that are less than 50 % methyl-esterified can form a gel-like structure and condense by cross-linking with calcium ions, which are present in primary cell walls. Degree of methylation, molecular weight, and pectin content are specific to fruit species (Table 10).

Table 10. Fruit pectin composition

Fruit	Pectin, wt %	Methylation wt %
Apple	0.5 – 1.6	80 – 92
Blackcurrant	1.0 – 1.2	50 – 80
Grape	0.1 – 0.4	50 – 65
Orange peel	3.5 – 5.5	65
Pear	0.7 – 0.9	50 – 70
Pineapple	0.04 – 0.1	22 – 40
Strawberry	0.5 – 0.7	20 – 60

Figure 35. Fruit cells (fc) and middle lamellae (ml) connecting the cell walls
[Full View]

Figure 36. Model of pectin smooth regions (SR) and hairy regions (HR) model [483]. Ara = arabinose, Gal = galactose, GalA = galacturonic acid, Rha = rhamnose, Xyl = xylose.
[Full View]

These characteristics must be taken into consideration in choosing the right pectinase balance for best fruit processing. During ripening, the protopectin in primary cell wall is slowly transformed into soluble pectin by the action of endogenous pectinases present in the fruit. The decrease in molecular weight is due to pectin depolymerases, and the decrease in degree esterification mainly to pectin methylesterase. However, these activities are very low. Homogalacturonan contains chains of up to about 200 galacturonic acid units, 100 nm long, with some rhamnose. A xylogalacturonan subunit (XGalA), substituted with xylose at the C-3 position of the galacturonic acid residue, has been identified as part of the galacturonan backbone. It can be methyl-esterified. Rhamnogalacturonan I (RGI) has a backbone of up to 100 repeats of the disaccharide rhamnose-galactose. The side chain can vary in size from a single glycosyl residue to 50 or more glycosyl residues [482]. In general, about half of the rhamnosyl units of RGI have sidechains, but this can vary with cell type and physiological state.

Arabinans are mostly 5-linked arabinofuranosyl units forming helical chains, but arabinosyl units can be interconnected at each free O-2, O-3, and O-5 position to form a diverse group of branched arabinans [486]. The RGI of primary cell walls is branched with (1→5)- α-L-arabinan, (1→3)- or (1→2)- α-L-arabinosyl residues, and arabinogalactan (AG) type II with a (1→3),(1→6)- β-D-galactan backbone, with (1→3)- α-L-arabinosyl residues [487]. Other macromolecules such as cellulose, xyloglucan, and arabinogalactan proteins (AGP) are associated with the plasma membrane [488]. Rhamnogalacturonan II (RGII) is a low molecular weight (ca. 4.8 kdalton) complex polysaccharide with a backbone of nine (1→4)- α-D-galactosyluronic acid residues and four side chains attached to O-2 or O-3 of the backbone.

The side chains are composed of twelve different sugars [489] — apiose, 2-*O*-methyl-l-fucose, 2-*O*-methyl-D-xylose, aceric acid (3-*C*-carboxy-5-deoxy-l-xylose), Kdo (3-deoxy-D-manno-octulosonic acid), Dha (3-deoxy-D-lyxo-heptulosaric acid) — bound in more than 20 different linkages. The two main hemicelluloses of all primary cell walls are xyloglucan and arabinoxylan. Hemicelluloses bind tightly via hydrogen bonds to the surface of cellulose linking or cross-linking microfibrils to create a cellulose – hemicellulose network.

Interconnections with the pectic polysaccharides are of primary importance for the integrity of the pectin network. Cellulose is a (1→4)- β-D-glucan which accounts for about 20 – 30 % of the dry matter of most primary cell walls and is particularly abundant in secondary cell walls. In 1993-1994, VINCKEN and VORAGEN demonstrated that xyloglucan was a key structure of apple cell walls for the degradation of cell-wall-embedded cellulose (around 57 % of the apple cell-wall matrix) [490]. The cellulose – xyloglucan network determines the strength of the cell wall and is embedded in an independent pectin matrix, hemicelluloses, and proteins. In apples the xyloglucan fraction makes up about 24 % of the total amount of sugar. About 5 wt % of some primary cell walls is made up of the hydroxyprolin-rich structural glycoprotein extensin, which binds some polysaccharides together. Fractions of the different macromolecules in fruit are given in Table 11.

Table 11. Fruit cell wall composition in g/kg fresh matter

Fruit	EIR*	Pectin	Hemicellulose	Cellulose	Lignin	Protein	Total
Apple	20	272	169	349	2	76	868
Pear	15	281	148	267	69	82	847

Papaya	26	364	165	124	4	127	784

*Ethanol-insoluble residue.

Starch is present in unripe apples in amyloplasts. This is the largest biological molecule, with a molecular weight of 10^5 – 10^9 dalton. Starch is composed of two components: amylose and amylopectin [491]. Amylose, the minor component, is a (1→4)- α-D-glucan and has a linear structure. Various degrees of polymerization have been ascribed to this fraction, with chain lengths in the range of 100 – 1000 glucose units. Amylopectin contains α-(1→6) and α-(1→4) glucose linkages. Amylopectin exhibits branching at the 1→6 position, and its degree of polymerization is far higher than that of amylose. The ratio amylose/amylopectin can vary in natural starches in the general range 1/3 to 1/4.

5.1.2.3. Cell-Wall-Degrading Enzymes

Pectinases. Progress in enzymology has been so fast that certain activities are not yet described in the International Enzyme Classification (E.C. no.). Many microorganisms produce enzymes that degrade fruit cell walls. Commercial pectinases for the fruit juice industry come from selected strains of *Aspergillus* sp. Enzymes are produced during fungal growth, purified, and concentrated. Pectinases are defined and classified on the basis of their action toward pectin (Fig. 37). Pectin lyase (PL, E.C. 4.2.2.10) is a pectin depolymerase of the endo type which has a great affinity for long, highly methylated chains and acts by β-elimination of methylated α-1,4 homogalacturonan with the formation of C4-C5 unsaturated oligo-uronides [492]. Pectin methylesterase (PME, E.C. 3.1.1.11) removes methoxyl groups from pectin, and at the same time decreases the affinity of PL for this substrate. This results in the formation of methanol and less highly methylated pectin. PME from *Aspergillus* has a strong affinity for highly methoxylated pectin such as apple pectin and acts according to a multichain mechanism [493]. Demethylation with PME generates free carboxylic acid groups and the pectin becomes negatively charged. Polygalacturonase (PG, E.C. 3.2.1.15) exists in two forms: endo-PG and exo-PG. Both types act only on pectin with a degree of esterification of less than 50 – 60 %. Endo-PG acts randomly on the α-1,4-polygalacturonic backbone and results in a pronounced decrease in viscosity. Exo-PG acts at the nonreducing end of the chain. Exo-PG releases small fragments from the chain and does not significantly reduce the viscosity.

Figure 37. Fruit pectin and pectin-degrading enzymes. Ara = arabinose, Gal = galactose, GalA = galacturonic acid, OMe = methyl ester, OAc = ethyl ester, Rha = rhamnose, Xyl = xylose. [Full View]

Seven endo-PGs, two exo-PGs, and seven PL isoenzymes from *Aspergillus niger* have been described [494], [495]. Different enzymes acting on rhamnogalacturonan I were identified and purified from *Aspergillus* sp. [496]. RGase A was identified as a hydrolase that splits the α-D-GalA*p*-(1→2)- α-L-Rha*p* linkage of RGI, while RGase B appeared to be a lyase that splits the α-*l*-Rha*p*-(1→4)- α-D-GalAp linkage by β-elimination. Two novel enzymes were also identified: a rhamnogalacturonan rhamnohydrolase and a rhamnogalacturonan galacturonohydrolase. As an accessory enzyme for the RGases, rhamnogalacturonan acetyl esterase (RGAE) was also described. Although the structure of RGII substrate has been described, enzymes able to hydrolyse it are still unknown and have not been described yet (2003).

Arabanases are pectinases, since they remove arabinose covalently bound to the homogalacturonan backbone. Three enzymes have been described: an endo-arabinanase (α-1→5; ABFA) and two arabinofuranosidases, namely, exo-arabinofuranosidase A (α-1→2; α-1→3) (ABFA) and exo-arabinofuranosidase B (α-1→3; α-1→5; ABFB; E.C. 3.2.1.55). All three are produced by *Aspergillus niger* [497]. High activities are required for apple and pear processing. In general, pectinase activity and ratio of the different pectinases can vary in different commercial preparations.

Hemicellulases. Hemicellulases are enzymes that hydrolyze arabinogalactans, galactans, xyloglucans, and xylans. Arabinanases are classified as pectinases when they act on pectin side arabinans. They are also classified as hemicellulases when acting on arabinogalactans or arabinoxylans. *Aspergillus* sp. produces enzymes that hydrolyse arabino-(1→4)- β-D-galactans type I and arabino-(1→3)-(1→6)- β-D-galactans type II [487], [498], [499].

The exo-(1→3)- β-D-galactanase is able to release galactose and (1→6)- β-D-galactobiose. *Aspergillus* enzyme is able to bypass a branch point in a β-(1→3) backbone. The action of this enzyme is enhanced by the presence of ABFB. Xylanases hydrolyse the (1→4)- β-D-xylans in synergy with ABFs [500].

Amylases. In fruit juice industry, fungal acid amylase and amyloglucosidase are used to process fruits which contain starch. This is the case for unripe apples at harvest time. *Aspergillus niger* produces acid α-amylase and amyloglucosidase [501]. These exogenous enzymes are applied after starch gelatinization (occurring above 75 °C) for preventing post-bottling haze formation (starch retrogradation). Acid endoamylase (AA) acts on amylose and amylopectin. It produces dextrins, which are substrates for glucoamylase or amyloglucosidase (AG) α-1→4,1→6 exo-hydrolase, which release glucose from the non-reducing end of the chain.

5.1.2.4. Apple Processing

After oranges, apples are the most important raw material worldwide for the production of clear juice and clear concentrate. About 54 × 10^6 t/a of apples are gathered, and about 10 % are processed to produce mostly clear concentrate, and 2 % as cloudy juice, cider, and apple sauce [502]. The major producers of apple juice concentrate are located in the USA, Poland, Argentina, Italy, Chile, Germany, and China.

5.1.2.4.1. Apple Pulp Maceration

The current trend is to process apple juice from table varieties having defects or not sold for table consumption (Golden Delicious, Granny Smith, Jonagold, Red Delicious). Apples processed in the crop period are easily pressed with a relatively high yield. They are stored at low temperature in controlled atmosphere for several months and processed according to market demand. During storage, the insoluble protopectin is slowly transformed into soluble pectin by endogenous apple pectinases (protopectinase type), and starch is slowly degraded by endogenous apple amylases into glucose and consumed during post-harvest metabolism. Soluble pectin content can increase from 0.5 up to 5 g per kilogram of over-ripe apple [503]. Apples become difficult to press unless macerated with pectinases (Fig. 38). In the traditional process,

enzymes are used at two different stages (Fig. 39). Application of commercial pectinases from *Aspergillus* sp. in apple mash is necessary because activity of endogenous enzymes is too low to cause an immediate noticeable effect. Because apple pectin is highly methylated, commercial enzyme preparations must contain a high concentration of pectinlyase or pectin methylesterase in association with polygalacturonase and arabanase, together with side activities such as rhamnogalacturonase and xylogalacturonase. Rapidase Press (DSM), Pectinex UltraSP (Novozymes), and Rohapect MA+ (Röhm) pectinases sold for apple pulp maceration contain enzymes necessary to obtain a good pressability and high yield throughout the entire season. Commercial products contain more or less the enzyme activities described below, but with different ratios from non-GM and GM organisms.

Figure 38. Effect of pectinases on percentage apple juice yield during the processing season
[Full View]

Figure 39. Production of apple concentrate
[Full View]

Pulp enzyming results in a fast decrease in pulp viscosity, a large volume of free-run juice, and fast pressing. The yield is over 90 % with hydraulic press and pomace leaching, compared to 75 – 80 % maximum without enzyme treatment.

5.1.2.4.2. Apple Juice Depectinization

Pectin is the main cause of juice turbidity. One liter of juice with 13 % dry matter can contain 2 – 5 g of pectin after pressing, depending on the ripeness of the fruit. Pectinase dosage is determined in the laboratory by performing the alcohol test. Use of acidified ethanol (2 volumes of ethanol containing 0.5 % HCl + 1 volume of apple juice) to precipitate residual pectin with a molecular weight of up to 3000 dalton. It is important to use acidified ethanol; otherwise, precipitation of organic acids or calcium pectate occurs because of the pH change after mixing ethanol with the juice, and thus a a false positive result is obtained. Pectinlyase or pectin methylesterase plus polygalacturonase and arabanase are the most important enzymes. Arabinose represents 55 % of neutral sugars in hairy regions of apple pectin. Arabanase activity prevents haze formation after juice concentration. The juice clarification is carried out after enzymatic depectinization [504]. The first stage consists of destabilization of the cloud by PL, which has no visible effect but results in a strong decrease in the viscosity of the juice (Fig. 40). PL cuts pectin at random, and cutting 1 – 2 % of the linkages is enough to reduce apple juice viscosity by 50 %. PG becomes active only after the action of PME. Because of its high molecular weight, PG cannot hydrolyse pectin with a degree of methylation greater than 50 – 60 % due to steric hindrance. At this stage, PL is no longer active and pectin hydrolysis is due to the system PME/PG. The second stage is cloud flocculation. The sedimentation necessary for the clarification of apple juice occurs only after enzymatic degradation of pectin and starch. The cloud is composed of proteins that are positively charged at the pH of the juice (3.5 – 4.0) since their isoelectric point lies between pH 4.0 and 5.0. These proteins are bound to hemicelluloses that are surrounded by pectin as a negatively charged protective colloid layer. Pectinases partially hydrolyze the pectin gel, and thus results in the electrostatic aggregation of oppositely charged particles (positive proteins and negative tannins and pectin), flocculation of the cloud, and then clarification of the juice [504]. The optimal pH for this mechanism is 3.6. The alcohol test shows whether juice depectinization is complete.

Figure 40. Apple juice depectinization
[Full View]

At the beginning of the processing season, unripe apples contain 5 – 7 g of starch per liter of juice. At this point, the iodine test gives a dark blue color and starch can be precipitated with iodine. Starch is present as granules 2 – 13 µm in size, composed of 30 % amylose and 70 % amylopectin chains. The latter can fix 20 wt % iodine. Apples contain endogenous amylases, but the process is too short and activities are too low to degrade the starch. When the juice is heated to 75 – 80 °C, starch changes from an insoluble form to a soluble form (gelatinization with water). If no amylase is added, these molecules can subsequently undergo retrogradation and form large aggregates that are difficult to hydrolyze and clog filters. The addition of fungal amylase and amyloglucosidase results in the hydrolysis of soluble starch into glucose monomers. Retrogradation and post-bottling haze formation are prevented, and clarification and filterability are improved. Preparations such as Hazyme DCL (DSM) and AMG (Novozymes) contain α-amylase and amyloglucosidase from *Aspergillus niger*. The dosage is determined by the iodine test. The third stage is clarification with finings and sheet filtration, which is being replaced by micro- or ultrafiltration (UF). Inorganic membranes have cut-offs from 20 000 to 500 000 dalton. Insoluble particles and soluble undegraded molecules such as parts of RGI, RGII, proteins including enzymes, and polyphenols, remain to a greater or lesser extent in the retentate, depending on the cut-off of the filtration membrane. Recently, it was found that undegraded RGI, RGII, and dextrins can foul UF membranes. Rapidase UF (DSM) and Novoferm 43 (Novozymes) contain rhamnogalacturonases and other side activities to improve ultrafiltration flow rate.

In conclusion, apple juice is easily produced after pulp maceration and juice depectinization with enzymes, with possible concentration of up to 70° brix (percentage by weight of soluble solids in a syrup at 68 °F), without risk of gel or haze formation. A few producers make “natural” or cloudy apple juice, e.g., in Germany and the USA. Until now, they did not add enzymes, because the existing commercial pectinases induce fast clarification of the juice. DSM sells a purified pectin methylesterase without pectin depolymerase activity. It can be used in the cloudy-juice process at the maceration stage to improve the yield, and also in the French cider process with calcium for defecation with flotation techniques.

5.1.2.5. Red-Berry Processing

The production of clear juice and concentrate from blackcurrant, raspberry, or strawberry requires enzymatic maceration and depectinization [505], [506]. Clarification, filtration, and concentration are difficult because these juices have high pectin content (typical content of residual low molecular weight pectin of 7 g L^{-1} compared to 0.5 g L^{-1} in apple juice). It is assumed that pectin hairy regions remain as soluble colloid in the juice and hemicelluloses tend to bind to phenolics and proteins during processing and storage. The result is the formation of irreversibly linked brown complexes that enzymes can no longer break down. An additional problem is related to the frequent contamination of red berries, mainly strawberry and raspberry, with *Botrytis cinerea*. This parasitic fungus, growing on rotten berries, secretes a β-1,3-1,6-linked glucan into the berries with a molecular weight of ca. 10^6 dalton [507]. This gum reduces the filterability and the clarity of the juice. It is possible to hydrolyze this glucan with β-glucanases with Glucanex (Novozymes).

Single-Stage Red-Berries Process. The single-stage process consists of simultaneous blackcurrant or blackberry maceration and depectinization (Fig. 41). Pectinases are used to improve juice and color extraction while retaining the organoleptic properties of the fruit. However, the extracted color is sometimes partly destabilized by anthocyanases (side activities of pectinases) or by oxidation. Oxidation can be chemical or enzymatic, due to the endogenous polyphenol oxidase (PPO) of the fruit, and is catalyzed by metal ions. It is therefore recommended that the pulp be heated to 90 °C to inhibit fruit oxidases prior to maceration with enzymes. Some red berries are very acidid (pH 2.6 – 2.8) and have high contents of phenolics and anthocyanins, which are inhibitors of pectinases. Hence, red-berry processing requires commercial pectinases that are especially stable under these conditions.

Figure 41. Production of blackcurrant concentrate
[Full View]

Two-Stage Red-Berries Process. The two-stage process consists of enzymatic maceration of fruit pulp, followed by a second addition of enzyme for juice depectinization at low temperature. Raspberries or gooseberries are heated to 90 °C for at least two minutes to increase color extraction and to destroy fruit polyphenol oxidase. The pulp is then cooled to 20 – 25 °C for enzymatic maceration. After pressing, the extracted juice is depectinized with pectinases. The low processing temperature after heating prevents aroma losses, and high-quality juices and concentrates can be produced. In the case of strawberries, it is appropriate to heat the pulp because it would create an unpressable purée, aromas loss, and juice browning. Hence, strawberries are processed at ambient temperature [506].

5.1.2.6. Tropical Fruit and Citrus Processing

Tropical Fruit. Tropical fruit is mainly processed to purée and stored before further processing to cloudy or clear juice. Fruit purée, cloudy or clear juice from apricot, peach, kiwi, mango, guava, papaya, and banana are often processed without enzymes. The main problem is viscosity, which can be decreased with pectinases [502]. Pectinases and amylases can be later used for clear juice production.

Citrus Fruits. The development of frozen concentrated orange juice started in 1940. Orange juice is the most consumed fruit juice in the world. Citrus fruit processing includes exploitation of all byproducts, among which pectin and essential oils are the most significant (Fig. 42). Although in certain countries it is not permitted to use enzymes in the production of premium orange juice, they can be used in other applications. Enzymes can increase the yield of solids recovery during pulp washing, facilitate the production of highly concentrated citrus base, improve recovery of essential oil from peel, debitter juice, and clarify lemon juice [502]. An example of citrus processing using enzymes is fruit peeling. The whole orange or grapefruit is treated with pectinases for digestion of albedo (the white, inside part of the peel), which binds flavedo (the orange or yellow, outside part of the peel). The fruit peel is scored and whole fruits are treated with a 2 % pectinase solution by vacuum infusion technology. After vacuum break, fruits are maintained at 40 °C for 15 – 60 min for albedo digestion inside the fruit. Peeled fruits are then rinsed, cooled, and packed.

Figure 42. Citrus processing
[Full View]

Another example is the production of clear lemon concentrate. Cloudy lemon juice coming from the extractor contains particles composed of pectin and proteins remaining in suspension and binding citral aroma (predominant lemon flavor). Clarification of lemon juice was achieved in the past by addition of large amounts of bentonite or sulfur dioxide. Today, clarification can be carried out with the very acidic pectinase Clarex Citrus 8XL (DSM), which degrades the pectin part of the cloud. Enzymes are added to the juice in amounts of 10 g hL^{-1} at 8 – 10 °C to avoid juice oxidation. The insoluble solids are removed by filtration or ultrafiltration. The brilliant lemon juice can be concentrated at 65° brix.

5.1.2.7. Conclusion

Nowadays, enzyme producers provide a wide range of pectinases for processing of fruit to give various products such as puree, cloudy juice, clear juice, and concentrate. The evolution of technology and processes including enzymes allow processors to obtain higher juice yield (productivity) together with higher quality of finished products. The use of specific pectinases adapted to the fruit process improves the shelf life of juices and concentrates (stability of color and freedom from turbidity). Apart from juice processing, the wide range and the high specificity of commercial enzymes open the way to new processes and new types of fruit-derived products. The trend is to process fruit under milder and more strictly controlled conditions to obtain new fruit products with sensory characteristics closer to those of fresh fruit.

However, because processing technology evolves faster than regulation, it is necessary to define food standard values and process references (equipment, process stages, type of enzymes . . .). In Europe, a Code of Practice has been developed to maintain quality and authenticity standards [508]. Members of

Association of the Industry of Juices and Nectars from fruits and vegetables (AIJN) in parallel with the Association of Microbial Food Enzyme Producers (AMFEP) have established references for fruit juice composition and enzyme specifications, in line with commercial standards and regulations of different countries.

5.1.3. Enzymes in Brewing

5.1.3.1. Introduction

Brewing is an old and traditional process that uses a variety of raw materials; in centuries past, many brewing processes have evolved, and they show the versatility and craftmanship of historic brewmasters. By far the most important brewing style is the “lager” type, characterized by the use of very pure water, low-temperature fermentation, and a long maturation period. Even in this relatively young beer style, many variations have developed; however, the variety of temperature programs during mashing, types of filtration, etc. are treated elsewhere (see → Beer). The common denominator in the brewing of beer is that part of the starch of a cereal is converted into alcohol. In the first stage enzymes hydrolyze starch into fermentable sugars. In a second process stage, these sugars are converted to alcohol and carbon dioxide by yeast. (Not all beers use yeast for fermentation; e.g., in the case of gueuze beers and weissen, bacteria are involved.)

The traditional source of enzymes used for the conversion of cereals into beer is malted grain, and malted barley is a key ingredient in brewing. Malting depends on many factors, including the barley variety and quality, the malt kilning regime and the skill of the malter. The extent and success of the malting process depends on the development, distribution, and survival of indigenous barley enzymes, and in the case of the notoriously heat labile malt enzymes, quality varies from season to season and from region to region.

During the malting of barley a series of enzymes — proteases, amylases, glucanases, and cellulases — developes in the malt. Enzymes such as β-amylase, exo-peptidase, and carboxy-peptidase are present in the starchy endosperm of the barley, and are activated during malting. In the aleurone layer of the barley, β-glucanase, endo-proteases, α-amylase and pentosanases are formed during malting. The formation and activation of the enzymes is promoted by increasing moisture and oxygen concentrations during the steeping process, and is then fixed by the kilning of the green malt. At this stage each enzyme with its individual properties is present at its individual concentration.

Detailed steps of the brewing process are never universal due to their wide variety in both starting material, brewing style, and technical preferences and possibilities. In this chapter a simplified brewing scheme is adopted (Fig. 43):

- Milling: reducing the size of the dry malt
- Mashing: adding water to the malt; controlled rise of temperature to allow enzymes to degrade proteins and carbohydrates
- Brewing: boiling the mash
- Filtration:separate spent grain and most (lautering)
- Cooling of the most
- Fermentation: convert sugars into alcohol and carbon dioxide
- Filtration: separate yeast from bright beer
- Maturation: settling of insolubles, reduction of vicinal diketones
- Packaging: in casks, kegs, bottles, cans
- Pasteurization: improving microbiological stability

Figure 43. Schematic of the brewing process
[Full View]

Of the steps in this schemes, four are directly affected by enzymes (mashing, fermentation, maturation, and

packaging); indirectly, the several filtration steps are strongly affected, too. Enzymes have an impact on several qualities of the final product, such as appearance, taste, and economics.

Starting from malt, the concentration of each enzyme will change to some extent during storage, milling, and steeping, i.e., before the mashing step. Each enzymes set of intrinsic properties (temperature stabilities, substrate affinities, pH dependences, etc.) does not change, but the expression of enzyme activity is dependent on the reaction conditions (time, temperature, pH [510], salts [511], other enzymes, etc.), i.e., the mashing conditions.

Since brewing, and therefore mashing, is a highly optimized process [512], there are several undesirable consequences if too little of an enzyme activity is expressed in the mash; for example:

- The extract yield is too low
- Wort separation takes too long
- Fermentation is too slow
- Too little alcohol is produced
- The beer filtration rate is reduced
- Off-flavour of the beer (diacetyl)
- Inferior stability of the beer

Auxiliary enzymes are used to supplement endogenous malt enzymes in order to solve or prevent these problems (see Section Enzymes for Problem Prevention or Solving). Furthermore, enzymes can be used improve the brewing process (e.g., better adjunct liquefaction, shortening of the beer maturation time, production of beer from cheaper raw materials; see Section Enzymes for Process Improvement). Finally, by using new enzymes it has become feasible to produce “nontraditional” types of beer (low-calory “light beer”, IMO beer, “sparkling wine”; see Section Special Brewing Processes)

5.1.3.2. Enzymes in Malting and Mashing

During the malting process, enzymes migrate from the aleurone layer into the starchy endosperm. Cell-wall material is degraded by hemicellulases and β-glucanase, and breakdown of proteinaceous material by proteases enables amylases to act on the starch granules. Each malt enzyme has its own set of intrinsic properties The most notable property is the dependency of both activity and stability on a host of physicochemical parameters [temperature, water quality (pH, salts), malt and adjunct concentration and composition, etc.]. The dependency is different for each enzyme. Figure 44a shows enzyme initial activity and stability (half-life time) as functions of temperature at two pH values. The action of an enzyme is determined by its capability to convert a substrate into a product (starch to maltodextrins, or protein to oligopeptides), that is, the integrated enzyme action over a period of time during which the enzyme simultaneously loses its enzymic function due to (e.g., thermal) instability. As a consequence, somewhere between temperatures too low for the enzyme to be highly active, and temperatures too high for the enzyme to survive, an optimum for the enzymic effect will occur. It is dependent on many physicochemical parameters, for example, pH, as illustrated by Figure 44b, or time (Figure 44c). Clearly, the optimum temperature is a derived variable and not an intrinsic property of an enzyme. In the end, it is the optimum overall process that will prevail over the fate of a single enzyme.

Figure 44. Enzyme activity as a function of various parameters
[Full View]

Figure 44. (*continued*) Enzyme activity as a function of various parameters
[Full View]

Figure 44. (*continued*) Enzyme activity as a function of various parameters
[Full View]

During mashing the situation is complicated, since some substrate molecules are formed by the action of one enzyme, and competed for by another enzyme, and these figures are based on a highly simplified model.

Figure 44d shows such a simulation of product formation with time by a typical enzyme at constant temperature, and Figure 44e over a temperature course typically used in a double-decoction mashing procedure. These graphs illustrate how conditions (e.g., temperature) for this enzyme might not completely ideal during mashing, and that a shorter mashing time would optimize the economics of this enzyme.

As a further illustration, Figure 44f and Figure 44g show that for another typical enzyme, a longer mashing period at lower temperature would be better suited.

Since many enzymes act simultaneously, and the results [e.g., high FAN (free alpha amino nitrogen) vs stable foam] often contradict on the molecular scale, the mashing process is a balancing act between obtaining enough activity from one enzyme without destroying another before the goal of its action is achieved [513]. The simulation model in Figure 44e applies to a highly simplified case. In contrast to the simulation, the composition of the solution changes rapidly during real mashing, one enzyme uses the product of another's action as its substrate, proteases also destroy enzymes, and temperature and viscosity change. Even when using identical malt and mashing conditions, relatively small differences between brewing water qualities of two regions can already give rise to substantial differences in mashing results.

Although the mashing process may be too complicated to translate into a kinetic model, brew masters achieve excellent mashing results by skillfully balancing and adapting the many process parameters [514]. In mashing, a premeasured amount of grain is infused with a specific volume of strike water at a predetermined temperature, and the mash is stepped through a series of so-called temperature rests. It is the method used to reach the temperature of these rests which distinguishes the infusion from the decoction mashing methods, and for simplification each rest is given a name according to its major designated effect (Table 12).

Table 12. Rest periods in mashing

Temperature	Enzyme	Rest period	Duration
30 – 40 °C	phytase	acid rest	10 – 30 min
40 – 50 °C	protease	protein rest	20 – 40 min
60 – 66 °C	β-amylase	conversion rest	40 – 70 min
68 – 70 °C	α-amylase	conversion rest	20 – 40 min

The acid rest (see Section Improved Mashing Processes) is rarely employed and has been replaced by the use of brewing salts. The protein rest is used primarily with larger amounts of incompletely modified malts to produce amino acids (as nutrients for the yeast) and to break down other proteins (e.g., those that cause chill haze) without destroying the proteins that provide the beer with a good frothy head.

In some cases it can be economically or technically feasible to use exogenous enzyme activities to assist the endogenous malt enzymes, e.g., for the production of a special beer, or to cope with the effects of poor malt modification. A new balance has to be established between parameters such as time and temperature on the

one hand, and the combined effects of both endogenous and exogenous enzymes on the other. The combination of different enzymes can result in a more robust, faster, or more economical over-all production process. If malt has been replaced to a large extent by brewing adjuncts such as unmalted barley, corn grits, rice, or sugar syrups, the level of endogenous enzymes will be proportionally reduced, and the additional exogenous enzyme activities become an intrinsic part of the production process.

Sources of exogenous enzymes may be vegetal (papain), fungal (glucanase), or bacterial (protease). Industrial producers of enzymes have been using many sources from as early as the 1960s.

The wide variety of exogenous enzymes range from close-to-malt enzymes to enzymes originating from extromophile bacteria. With the use of bacterial enzymes, the latest achievements of modern biotechnology become available to the brew master. Enzymes hitherto unavailable are now economically feasible for use on an industrial scale, with only personal or commercial sentiments standing between the brew master and the deployment of enzymes from GM organisms.

A traditional all-malt lager brewing process is used as starting point where possible, and the next sections address three areas for using exogeneous enzymes:

1. Solving or preventing problems occurring during the brewing process (Section Enzymes for Problem Prevention or Solving),
2. Improving the brewing process (Section Enzymes for Process Improvement),
3. Enabling a nontraditional brewing process (Section Special Brewing Processes).

5.1.3.3. Enzymes for Problem Prevention or Solving

5.1.3.3.1. Bacterial α-Amylase in Mashing

The most important change brought about in mashing is the conversion of insoluble starch molecules into soluble, fermentable sugars and unfermentable dextrins. The principal enzymes responsible for starch conversion are α- and β-amylase. α-Amylase (E.C. 3.2.1.1) rapidly splits insoluble and soluble starch into many shorter chains that can be attacked by β-amylase (E.C. 3.2.1.2). In all-malt brewing, a maximum final mash temperature of 78 °C results in the best separation of wort from spent grain. By adding a bacterial α-amylase, the temperature can be increased to 85 °C in the final mashing phase. The exogenous enzyme extends the degradation of remaining starch into soluble oligosaccharides, continues to do so in the lauter tun, and thus prevents an increase in viscosity due to gelatinization of starch during wort separation. Adding thermostable bacterial α-amylase just before the mash is pumped into the lauter tun degrades any remaining starch. As the mash in the lauter tun is at a higher temperature, it is thinner and passes through the filter medium more quickly and smoothly.

Adding bacterial α-amylases becomes essential when a high fraction of adjuncts has diluted the concentration of endogenous enzymes in the mash tun. Since this dilution factor applies to all endogenous enzymes, additional enzyme dosage or enzyme cocktails containing, e.g., β-glucanase and protease in addition to amylase, are used.

If a thermostable bacterial α-amylase is used, brew masters often prefer separate addition of the β-glucanase and protease to add flexibility (compared to an enzyme cocktail with fixed composition) to adapt to their particular malt/adjunct situation.

5.1.3.3.2. Fungal α-Amylase in Fermentation

Slow fermentation can result from incomplete saccharification in the mashing process. If the problem is diagnosed in an early phase, direct addition of fungal α-amylase (E.C. 3.2.1.1) in the fermenter can correct the problem. The enzyme action at relative low temperatures lowers the attenuation limit (degree of attenuation is the percentage of fermentable carbohydrates in the wort extract), increases fermentability, and more alcohol is produced, resulting in a “drier” more attenuated beer.

5.1.3.3.3. β-Glucanase in Mashing

The β-glucanase (E.C. 3.2.1.4) from barley is very heat labile and survives for only a very short time at mashing temperatures. If not enough β-glucan is broken down, the remaining glucans will partly dissolve, bind water, and cause problems later in the process by increasing viscosity (and thus extending wort runoff

times) and by causing haze.

Optimizing the mashing process by varying temperature/time regimes often improves the performance of amylases and increases FAN values. If the new regime decreases β-glucanase performance, this may cause several related problems:

- Poor runoff,
- Poor extract recovery,
- Poor spent-grains drainage,
- Slow yeast sedimentation, poor centrifuge efficiency,
- Poor beer-filter performance, problems with haze.

β-Glucanases from, e.g., fungal origin, selected for improved thermostability under mashing conditions, result in a more robust and stable mashing process. They assist in the mashing of grists containing insufficiently modified or unevenly modified grains, aid runoff from the mash tun by reducing wort viscosity, and improve beer finability and filterability.

5.1.3.3.4. Cysteine Endopeptidases (Postfermentation)
If insufficient protein is removed by hot and cold precipitation (protein is needed throughout as, e.g., yeast nutrient, FAN, and for foam), polypeptides can cross-react with polyphenols during the final stages of beer production (conditioning, lagering) to cause an undesirable, so-called chill haze. Soluble proteolytic enzymes, such as papain (E.C. 3.4.22.2) and, to a lesser extent, bromelain (E.C. 3.4.22.32) and ficin (E.C. 3.4.22.3), are commonly used (mostly in conjunction with other stabilization agents such as poly(vinyl pyrrolidone) (PVP) or silica gels (e.g., Lucilite) before final filtration to improve the colloidal stability of the beer, and thus control chill haze in and increase the shelf-life of packaged beer. Papain, extracted from the fruit of *Carica papaya*, is effective in the temperature range of 30 – 45 °C and the pH range of 4.0 – 5.5. Added to conditioning tank, this a-specific endo-peptidase breaks down high molecular weight proteins that react with polyphenols before being destroyed during pasteurization.

The use of immobilized proteases has been studied, but has not been widely adopted.

5.1.3.3.5. Glucoamylase in Mashing
If the amount of dextrins remaining in the beer as nonfermentable sugars is too high, the addition of exogeneous glucoamylase (E.C. 3.2.1.3) to the mash tun results in cleavage of terminal α-1,6 glycosidic bonds of the oligosaccharides, and thus in an additional amount of fermentable glucose in the wort. Since glucoamylase only reacts with oligosaccharides of maximal 10 – 15 glucose units in length, this enzyme does not prevent starch hazes caused by high molecular weight amylose and amylopectin molecules.

5.1.3.4. Enzymes for Process Improvement
5.1.3.4.1. Adjunct Brewing
In adjunct brewing, malt is partly replaced by another starch source (e.g., corn, rice) for economical reasons or to produce a lighter taste. With malt as the sole enzyme source, the malt enzymes have a more difficult job since their relative concentration during mashing is lower. When higher percentages of adjunct are used a separate pre-mashing step with exogenous enzymes is introduced to enable a more predictable and simpler production process. As heat-stable amylases are much more stable than malt amylases, simpler liquefaction, shorter process times, and an overall increase in productivity can be achieved. Eliminating the malt from the adjunct cooker means less adjunct mash and thus more freedom in balancing volumes and temperatures in the mashing program.

Traditionally, the use of barley has been limited to 10 – 20 % of the grist when using high-quality malts. At higher contents of barley (> 30 %, or with low-quality malts) processing becomes more difficult, and the mash must be supplemented with extra enzyme activity (apart from α-amylase, some extra β-glucanase and endo-peptidase are needed) if the brewer uses unmalted barley while maintaining brewing performance. Other raw starch adjuncts are used to partially replace malt as the carbohydrate source. Adding thermostable bacterial α-amylase to the mash allows extension to the higher temperatures needed for liquefying starches from, e.g., rice or maize. Brewing systems that use raw starch or grits from rice, maize, or sorghum will have a separate cooking stage for these materials, preferably at elevated temperatures of up to 108 °C (jet cooking). Malt amylases are not suitable for this, and thermostable bacterial α-amylase, or a protein-

engineered more robust version thereof, is needed. Pre-gelatinized adjuncts, such as micronized cereals added to the mash need (nonthermostable) bacterial α-amylase to ensure that no residual starch is present in the worts. The enzyme hydrolyzes both malt and adjunct starches, liberating soluble dextrins. This action is supplemental to the action of the natural malt α- and β-amylases.

The presence of approximately 200 ppm Ca^{2+} is important when using nonthermostable α-amylase, especially when hydrolysis occurs at higher temperatures. Enzyme inactivation occurs when the temperature is raised to ca. 100 °C for 1 – 20 min. For all practical purposes the enzyme will be destroyed in the brewing kettle during wort boiling.

Liquid adjuncts as carbohydrate source include cane and beet sugar syrups, and the corn based DE (see Section Industrial Use) syrups produced by the corn starch processing industry. “Brewer's syrup” (a maltose syrup produced from, e.g., corn, with a carbohydrate spectrum close to that of sweet wort) has become popular as adjunct in the UK, South Africa, and some Asian countries. The solubilization and partial hydrolysis of corn starch is performed outside of the brewery by starch processors using modern industrial enzymes such as thermostable (protein-engineered) bacterial α-amylase, pullulanase, and β-amylase extracted from malt or barley. By using different saccharification reaction conditions (time, temperature, enzyme), by blending or by introducing fungal α-amylase and glucoamylase, starch processors can nowadays meet any brewer's syrup specification, both in composition and in economics.

5.1.3.4.2. Improved Mashing Processes

Proteases. The endogenous endo- and exo-proteases are highly heat labile and act mainly in the malthouse. Carboxy-peptidases are a little less heat sensitive, and continue to operate for a while in the mash. Proteases (and also β-glucanase) are quickly destroyed in an infusion mash at 63 – 66° C. When using decoction mashing techniques and a reduced initial mash temperature, significant enzyme activity can occur in the early stages of mashing. Therefore, malts for use in decoction mashing systems need not be so well modified as malts in infusion mashes. During the so-called protein rest (30 min at 40 – 50 °C) protease reduces the overall length of the high molecular weight proteins — the cause of foam instability and haze — to low molecular weight proteins in the mash. Endo-proteases split high molecular weight proteins into simpler peptides by breaking the peptide bonds between amino acids. Endo-proteases are responsible for degrading insoluble globulins, and albumins already dissolved in the wort, into medium-sized polypeptides. The reduction in content of albumins and globulins is important for reducing the haze caused both by proteins and polyphenols (tannins derived from the malt husks and hops). As a rule, reducing the number of large protein molecules in beer makes it less prone to haze. The medium-sized proteins are not useful yeast nutrients, but are important for foam stability and thus head retention, as well as for body or palate fullness. Some brewers prefer to limit the duration of the protein rest to improve the foam quality of the beer. A wide variety of endopeptidases are readily available; historically, the proteases originating from *Bacillus amyloliquefaciens* have proved adequate for in assisting the available malt proteases.

Pullulanase. Endogenous β-amylase (1,4- α-D-glucan maltohydrolase, E.C. 3.2.1.2) is an exo-enzyme that cleaves external α-1,4-glucosidic links to form maltose molecules and β-limit dextrins. The latter contain α-1,6-glycosidic links and cannot be cleaved by either α- or β-amylase; β-limit dextrins remain in the wort throughout fermentation as nonfermentable sugars. The natural enzyme produced in the wort that can cleave this link is limit dextrinase (dextrin α-1,6-glucanohydrolase, E.C. 3.2.1.142), a heat-labile enzyme that is readily inactivated at mashing temperatures. The exogeneous enzyme pullulanase (pullulan 6-glucanohydrolase, E.C. 3.2.1.41) hydrolyses α-1,6 glycosidic linkages in branched polysaccharides, e.g., amylopectin. The enzyme requires at least two α-1,4 glucose units to be on either side of the α-1,6 link, and thus maltose is the main final reaction product. The activity and stability of exogenous pullulanase must be compatible with mashing conditions, and not all industrial enzymes used in the starch processing industry qualify. The tolerance for fermentation pH values and limited thermostability prevent carry-through risk for pullulanase, and limit its action to achieving a set degree attenuation.

Phytase. The traditional acid rest used to be responsible for reducing the initial mash pH for traditional decoction mashing of lager beers starting from under-modified malt. The enzyme phytase from barley malt is active at 30 – 53 °C and breaks down insoluble phytin (a complex organic phosphate containing both calcium and magnesium) to phytic acid. The phytase reaction releases hydrogen ions in the process and may be accelarated and extended by adding a more thermostable phytase of bacterial origin. Highly modified

malts contain too little endegenous phytase because of the high kilning temperatures and depend fully on exogeneous phytase to achieve phytase-induced acidification, whether during the acid rest or during the intitial mashing phase at higher temperature. However, the acidity of highly kilned malts is normally sufficient to lower the mash pH without an acid rest.

Diastase/ β-Amylase. The most obvious method to enrich the enzymatic activity of malt is to add an extract of malt enzymes. Composition (concentrations of various enzymes) may vary between the various products, dependent on malt type and extraction processes. For economical reasons, addition of malt or barley extracts is only used if no high-quality malt is available and the use of bacterial and fungal enzyme is undesired.

5.1.3.4.3. Shelf-Life Improvement

During fermentation, yeast takes up all dissolved oxygen, and in the following processing steps the atmosphere in tanks and equipment is pure carbon dioxide. Typically the oxygen concentration in beer is below 200 ppm. After packaging, the concentration of oxygen in beer may vary from less than 500 to 1000 ppm. Traces of entrapped oxygen (and polyphenols such as delphinidin acting as pro-oxidants), lead to formation of the volatile aldehydes responsible for stale flavor in beer. Antioxidants, such as sulfite, ascorbic acid, and catechin, can thus protect beer from becoming stale in the presence of oxygen [517].

Various antioxidants have been added to green beer to either remove oxygen or to negate its effects. Ascorbic acid (vitamin C) at 1.5 g/hL reduces oxidation haze and the effect, similar to reducing dissolved oxygen. The reduction of agents containing sulfur can reduce chill hazes. Sodium hyposulfite has some effect on chill haze when used in amounts of 20 ppm, and sodium metabisulfite and ascorbic acid (10 – 20 ppm each) have a synergistic action in protecting the activity of papain in beer during and after pasteurization. In contrast to the reducing agents, which are needed in equimolar amounts to the dissolved oxygen, enzymatic oxygen removal uses the small concentration of available glucose as the electron donor to scavenge oxygen. The removal of oxygen by glucose oxidase (β-D-glucose:oxygen 1-oxidoreductase, EC 1.1.3.4) plus catalase (H_2O_2 oxidoreductase, EC 1.11.1.6) is the sum of two reactions: glucose oxidase converts glucose and oxygen to gluconic acid and hydrogen peroxide, which is transformed by catalase into water and oxygen (net reaction: glucose +1/2 $O_2 \rightarrow$ gluconic acid).

In practice, a system with only enzymic deoxygenation is less efficient than a combination of enzymes and chemical reductants. The concentration of free glucose in beer may be too low for effective removal of oxygen, but it was demonstrated [518] that by adding only glucose oxidase and sulfite successfully suppressed the flavor deterioration of the beers. Another possibility is that the peroxide formed in the first reaction, and/or intermediates leading to oxygen formation in the second reaction, are reactive and responsible for oxidative deterioration of beer flavor [519].

5.1.3.4.4. Accelerated Maturation

Lagering involves secondary fermentation of remaining fermentable extract at a reduced rate at low temperatures and low yeast count. The low temperature promotes the settling of remaining yeast and precipitation of haze-forming material (protein/polyphenol complexes). The maturation period or diacetyl rest reinvigorates the yeast culture so that it metabolizes byproducts such as diacetyl and 2,3-pentanedione that were excreted early in the fermentation. During the maturation period 96 % of the diacetyl and 2,3-pentadione is used in biosynthesis (i.e., amino acid valine/leucine synthesis in particular) by active yeast and 4 % of α-acetolactate formed in beer is oxidized to diacetyl. The flavor threshold for diacetyl is 0.10 mg/L, and this small molecule causes an unpleasant buttery or butterscotch taste, considered a major off-flavor for lager-type beer.

Depending upon the yeast type, the physical environment, etc., this process takes 5 to 7 weeks with traditional lagering. Employing a diacetyl rest is particularly important when producing beers with high adjunct fraction due to the high levels of diacetyl produced [520]. It is also important in brewing lagers, as they do not have a heavy flavor impression.

In accelerated lagering the beer is fully attenuated, virtually free of yeast, and stored at higher temperatures to reduce the concentration of vicinal diketones, which are responsible for off-flavors in beer. Accelerated lagering reduces the time needed to achieve a product similar to beer brewed with a cold-lagering process to 7 to 14 d, with the same clarity and flavor stability [521]. Sometimes freshly fermenting wort is added to

diacetyl-laden beer in cold storage (kräusen) so that active yeast absorbs diacetyl.

With the exogenous enzyme α-acetolactate decarboxylase (ALDC, (*S*)-2-hydroxy-2-methyl-3-oxobutanoate carboxylyase, E.C. 4.1.1.5) the excess α-acetolactate can be directly converted into harmless butanediol, bypassing the formation of diacetyl.

By eliminating one of the major reasons for an extended lagering period, ALDC enables brewers to extend their peak lagering capacity.

5.1.3.4.5. Starch-Haze Removal
Fermentation problems, such as sticking fermentations or unacceptably low attenuation limits, are only noticed after mashing, when certain notable fermentation parameters are not met. Undegraded starch or high molecular weight carbohydrates that will neither fine nor ferment out, rearrange into insoluble complexes that cause beer with a starch or carbohydrate haze. Under these circumstances it is important to apply corrective action swiftly to avoid atypical flavor profiles. At the lower temperatures common in fermentation, fungal α-amylases are capable of rapidly hydrolyzing the interior α-1,4-glucosidic linkages of barley, malt, and cereal starch and the formation of maltose and a carbohydrate profile similar to that derived from indigenous malt amylases.

5.1.3.5. Special Brewing Processes
Low-calory beer (diet/light lagers) is based on the American lager style of brewing. Corn is the major adjunct, amounting to 50 – 65 % of the total grain bill, and processed with added enzymes, e.g., glucoamylase to break down nonfermentable carbohydrates and attenuation is higher than normal beers. *Dry beer*, *super dry beer*, and *sparkling wine* are highly carbonated fermentation products with almost complete conversion of all carbohydrates into alcohol and CO_2 assisted by bacterial and fungal enzymes. The main starch source in *sorghum beer* (bantu or kaffir beer, pombe, burukutu, pito), is unmalted sorghum, supplemented with maize. After acidification with lactic acid to lower the pH to 4, bacterial α-amylase may be added, and the cooker is heated to boiling for 90 – 120 min. After cooling to 60 – 62°C, malted sorghum and/or bacterial glucoamylase is added for a partial saccharification. After coarse filtration and cooling to 30 – 35 °C, yeast is added. The fermenting turbid mash is packed in open bottles, jerrycans, or vessels, ready for consumption after 16 – 24 h. Still experimental is the production of *IMO beer*. The consumption of isomaltooligosaccharides (IMO: glucose oligomers with α-1,6-glucosidic linkages) is claimed to stimulate the health-promoting activity of colonic bacteria of genus *Bifidobacterium*, as well as producing a mild sweet taste and low cariogenic properties. IMO-containing syrups are usually produced from starch by means of cooperative reactions, one of which is transglycosylation catalyzed by (immobilized [522]) enzymes of microbial origin, by conversion of high-maltose syrup into IMO-containing syrup. The transglycosylation product contains about 38 % of panose, 4 % of isomaltose, 28 % of glucose and 23 % of maltose, and the usage of IMO syrup in the brewery to replace maltose imparts functional properties to traditional food products with minimal changes in production technology and product taste. By introducing transglucosidase (EC 2.4.1.) during an enzyme assisted mashing process, it is also possible to produce IMO *in situ*.

High-gravity brewing involves worts of up to 18 °P and even higher. After fermentation and maturation, the beer is diluted with cold carbonated water to the designated gravity or to a prescribed alcohol concentration. Advantages associated with high-gravity brewing are that it results in beers that are more consistent (alcohol content, original gravity, etc.) and more physically stable because the compounds responsible for haze are more easily precipitated at the higher concentrations [523]. Handling more concentrated wort results in increased utilization of equipment and lower energy costs The disadvantages are problematic mashing, longer fermentation times, different flavor characteristics, and poorer hop utilization than normal-gravity fermentations [524]. Exogenous enzymes are used to assist in mashing (neutral protease, bacterial α-amylase) and fermentation (fungal α-amylase).

5.1.4. Enzymes in Dairy Applications
5.1.4.1. Introduction
Dairy products are among the classic examples of fermentation-derived foodstuffs, and their history of development goes back several millennia. Through the ages a huge variety of dairy products has been developed based on empirical experimentation. Profound understanding of biochemical, microbiological,

and physicochemical processes has mainly been achieved during the second half of the 1900s. Economical interest and scientific progress have led to the development of dairy food science as a special branch within food science, and it is the basis of control in manufacturing a huge variety of dairy products. Emphasis on understanding and controlling taste and texture development has led to a still growing assortment of cheeses and desserts. Enzymes originating from raw materials, microbial starter cultures, or other sources are prime tools in improving existing and creating novel dairy products.

5.1.4.2. Cheesemaking

5.1.4.2.1. Cheesemaking Process

A basic element in the process of cheesemaking is the clotting of the milk. Milk turns into a gel structure through the action of coagulating enzymes, briefly called coagulants. The casein proteins in milk lose their colloidal stability and aggregate to form a gel structure. After cutting of the gel, the liquid whey fraction, containing whey proteins, minerals, and lactose, separates from the casein chunks. The casein material, the curd, is collected in molds. After pressing and brining, the cheese is kept under conditioned storage for ripening. Storage time may last from weeks to months, even years, depending on the type of cheese.

5.1.4.2.2. Mechanism of Renneting

About 80 % of milk protein consists of casein, which is hydrophobic by nature. The bovine caseins may be subdivided in four species of phosphoproteins that exist, due to their poor solubility in water, in agglomerates. The four species αs_1-, αs_2, β- and κ-casein occur in relative molar concentrations of about 4:1:4:1.6. Caseins aggregate to form submicelles, which together form the casein micelle [525]. The outer surface of the casein micelle consists of submicelles containing a relatively high content of κ-casein molecules. Hydrophilic, negatively charged parts of the κ-casein molecules protrude from the periphery of the micelle and guarantee micelle stability due to electrostatic and entropic repulsion. The coagulating enzymes specifically split off a distinct part of these κ-casein hairs, hydrolyzing the Phe-Met bond (at amino acid 105 – 106) and thus provoke destabilization of the whole micelles, which aggregate with each other. The part of κ-casein split off is called the caseino macro peptide. Calcium ions facilitate casein micelle aggregation but do not affect the enzyme reaction. The enzyme reaction is very sensitive to pH but less to temperature. The aggregation rate is strongly affected by temperature between 25 and 35 °C. Renneting is thus described by the enzymatic reaction and by Casein Micelle Aggregation [526], [527].

5.1.4.2.3. Types of Coagulants

Commercially available coagulants used in the cheesemaking industry consist of animal rennet and microbial coagulants from non-GM and GM microorganisms. Animal rennet is obtained from the gastric mucosa of young mammals, usually of bovine origin. Animal rennet is a mixture of chymosin and pepsin (E.C. 3.4.23.1). The ratio of chymosin to pepsin depends on the age of the animal, being highest (about 95 %) for unweaned calves. The high ratio of chymosin to pepsin in the calf stomach is explained by the fact that chymosin does not hydrolyze immunoglobulins, which are present in the colostrum and needed to build up immunity, whereas pepsin does.

Due to the limited availability of calf rennet, substitutes from microbial sources have been sought, and nowadays microbial coagulants cover a considerable part of the demand for of coagulating enzymes worldwide. Microbial coagulants are produced by fermentation. Most widely applied are enzymes from *Rhizomucor miehei*, *Rhizomucor pussilus*, and *Cryphonectria parasitica*.

A third group of coagulants is made by genetically modified microorganisms. The bovine gene encoding for chymosin type B is cloned in the genome of fungi and yeasts such as *Aspergillus oryzae* and *Kluyveromyces lactis*. Chymosin type A cloned and expressed in *E. coli* is no longer commercially available. Several efforts have been made to clone microbial genes from *R. miehei* or *R. pussilus* in other microbial expression hosts, but, although technically feasible, none of these have reached commercial application.

In some minor cheese types plant proteases from cardoon and *Solanum dobium* are used.

Coagulants are commercially available in liquid, powdered, tabletted, and paste formulations of varying strengths. Animal rennets are made in standardized ratios of chymosin to pepsin.

5.1.4.2.4. Properties of Coagulating Enzymes

All coagulating enzymes are aspartic endoproteases. Two aspartic acid residues are located in the active center of the enzyme and play an essential role in the proteolytic mechanism. All coagulating enzymes are more or less inhibited by pepstatin, a microbial oligopeptide from strains of *Streptomyces* [528]. Coagulants are of comparable size and three-dimensional bilobal, structure and contain highly conserved regions. The amino acid homology between microbial coagulants is high, but they diverge extensively from mammalian ones [529]. The three-dimensional structures have been elucidated by crystallographic studies [530]. Chymosin and pepsin are secreted as inactive zymogens, whereas the microbial enzymes are not. In low-pH environments, as in the stomach, the propeptides are split off to activate the enzyme. Table 13 lists some biochemical characteristics of coagulating enzymes.

Table 13. Biochemical characteristics coagulating enzymes

Coagulant	Source	E. C. no.	M, kDa	IEP	Glycosylation	T_{opt}. °C (milk clotting)
Chymosin	bovine	3.4.23.4	35.7	4.98	no	40–44
Mucorpepsin	*R. miehei*	3.4.23.23	38	4.58	yes	58–62
Mucorpepsin	*R. pussilus*	3.4.23.23	30–39	4.41	yes	42–45
Endothiapepsin	*C. parasitica*	3.4.23.22	33. 8	4.89	no	42

Chymosin in animal rennet consists of types A and B, which are point-mutated at position 290, where chymosin A has Asp and chymosin B has Gly [531]. Chymosin A is said to have a higher specific activity for renneting but is less stable [532]. Due to its high specificity for cleaving the Phe-Met bond between amino acid residues 105 and 106 of κ-casein at the natural pH of cheese milk, chymosin is considered the standard renneting enzyme to which others are compared. At lower pH, aspartic proteases lose their specificity and aspecifically hydrolyze proteins randomly, even themselves. Apart from the coagulant from *C. parasitica*, which cleaves between amino acid residues 104 and 105 in κ-casein [529], the other coagulants also hydrolyze the Phe-Met bond of κ-casein. In general, microbial coagulants are more proteolytic than animal rennet. There are differences between the various coagulants in terms of the ratio of their milk clotting to their overall proteolytic activity, whereby a high ratio is important. The milk clotting to proteinase (also called caseinase) ratio (MC/PA) is used as a quality characteristic of coagulants [533]. These ratios vary with pH. At pH 6.5 chymosin derived through fermentation has the highest ratio, followed in order of decreasing ratio by calf rennet, bovine pepsin, and proteases from *R. pusillus*, *R. miehei*, and *C. parasitica*. The MC/PA ratio is directly related to cheese yield, one of the most important economical characteristics in the cheesemaking process. A high caseinase activity results in a relatively large amount of casein protein fragments that are washed away with the whey fraction and thus do not end up in the cheese curd. There is a huge, but also, conflicting amount of scientific literature describing comparison studies of cheese yield with different coagulants. In an elaborate study [534] the most relevant commercial coagulants were studied in a single comparable process (Table 14).

Table 14. Performance of commercial coagulants

Coagulant	Yield reduction, %
Calf rennet	0.0
Calf rennet/pepsin 1/1	0.09
Bovine rennet	0.14
Mucorpepsin (*R. pusillus*)	0.45
Mucorpepsin (*R. miehei*)	0.59
Endothiapepsin (*C. parasitica*)	1.11

Although the differences appear to be small, considering the huge amounts of milk processed, the economical relevance is considerable.

Heat lability is another important characteristic of coagulants [535]. For Emmental cheese, the cheesemaking process of which involves a cooking step at 50 °C to inactivate all residual coagulant in the cheese, mostly coagulant from *C. parasitica* is used because of its low heat stability. Any proteolytic activity of coagulants in whey, which is nowadays used in many food applications, should disappear following normal pasteurization (12 s, 72 °C). The following order of heat lability is known: porcine pepsin > bovine pepsin > *C. parasitica* > chymosin > *R. pusillus* > *R. miehei*. Commercial types of *R. miehei* coagulants have been chemically modified in order to lose stability and to meet application demands. The heat stability of all coagulants increases with decreasing pH.

5.1.4.2.5. Cheese Ripening

Cheese ripening [536] is mainly due to proteolytic breakdown of the casein protein. Endoproteases such as the endogenous milk enzyme plasmin and coagulating enzymes are responsible for the generation of casein polypeptide fragments. Plasmin is a trypsin-like alkaline endoprotease that occurs in milk also in its inactive plasminogen form. It is mainly associated with the casein micelle. Plasmin may become more or less active when plasmin- and plasminogen-activation inhibitors were separated with the whey fraction. Exoproteases, originating from the bacterial starter cultures, further break down part of these peptides to the level of free amino acids. These amino acids function as precursors for flavor compounds to be synthesized by the catabolic enzyme systems of the starter cultures. In this way the various types of starter cultures are responsible for the typical characteristics of cheese varieties. In this simplified description it is clear that coagulants play an important role in the ripening mechanism. At lower pH, as in cheese, coagulants become more and more aspecific. The various coagulants differ considerably in their ability to breakdown casein proteins. For that reason not all coagulants are suitable for all types of cheeses. Microbial coagulants are believed to be less suitable for long-ripening cheeses and are found to develop bitter off-flavors, although chemical modifications and processing optimization result in improved performance.

The separation of whey from curd is a crucial moment in the cheesemaking process in which retention of milk constituents in the curd is determined. Minerals and lactose are not retained in the curd. Particles such as bacteria and fat droplets are entangled in the casein network and end up almost entirely in the curd. The water present in cheese is mainly protein-bound and can not be regarded as a solvent. On the basis of partition calculations only a few percent of a water-soluble component present in milk would end up in the cheese. Retention of proteins is determined by the extent and nature of interaction of the proteins and casein. Whey proteins are completely expelled, but a lysozyme is fully retained. Retention of coagulants in the curd depends on the pH of the renneted milk at the moment of whey separation. Chymosin is retained to about 15 % at pH 6.5, which is a common pH in semihard cheesemaking (Gouda, Cheddar). In the Camembert cheesemaking process whey separation occurs at pH 6.2, and about 50 % of chymosin is retained. Under the same conditions retention of porcine pepsin is 65 %. Chymosin is electrostatically bound to the para-κ-casein part of κ-casein after having split off the caseinomacropeptide. This interaction, based on differences in isoelectric points of the two proteins, becomes stronger at lower pH [537]. The microbial coagulants are retained to about 18 % in curd, independent of pH [538]. As coagulants participate in the first stage of proteolysis in cheese the extent of retention is of significant importance for the rate of cheese ripening.

5.1.4.2.6. Cheese Flavors and Ripening Acceleration

For several semihard and hard cheese types long ripening, and consequently long storage times under strict temperature and humidity conditions, contribute substantially to the cost of cheese. For this reason, ripening acceleration has long been a topic of study. Acceleration of ripening can be achieved by changes in the process, addition of enzymes to the cheese milk, or by manipulation of lactic acid bacteria (LAB) from the so-called starter culture.

The most obvious way to accelerate ripening is by elevating the storage temperature. However, this results in unbalanced flavor and texture characteristics.

As cheese ripening is, for the most part, due to proteolysis of casein, addition of proteases would be an effective way to enhance ripening. The problem of addition of specific proteases, apart from finding the proper proteolytic specificities, is that proteases added to the cheese milk most often do not end up in the curd. Like whey proteins, extra added enzymes usually end up in the whey fraction. For this reason, specific formulation techniques, such as encapsulation in lyposomes, cross-linking, and entrapment of the proteases for targeting into the curd have been sought. In the Cheddar cheesemaking process, in which salt is added to the curd, addition of enzymes along with the dry salt presents an opportunity for addition, in contrast to many other cheese types. An uneven distribution of enzymes, resulting in “hot spots” in the cheese matrix may, however, result.

In practice the costly methods of formulation mean that the desired cost reduction is not achieved. Moreover, ripening acceleration results in a mature flavor that often does not match with the textural characteristics. Another approach to accelerate cheese ripening is by modification of starter cultures, both genetically or by composition. Addition of extra LAB is not feasible due to uncontrolled acidification of the cheese milk resulting in unwanted cheese characteristics. An elegant way may be the addition of attenuated starter cultures [539] in which the LAB have been killed by hot/cold temperature shock or by exposure to microwaves, but catabolic enzyme activities are still present. The problems of fast acidification of the cheese milk and low retention in curd have been solved in this way.

In the past the application of lysozyme (to lyse LAB in cheese) and lactase (to convert lactose into glucose and galactose, thereby offering other nutriants to LAB) have been studied, but did not result in commercial application.

Proteases and lipases have found commercial application in the production of spray-dried cheese-flavor protein derived from enzyme-modified cheese (EMC) processing. EMC is made of short-ripened, enzyme-inactivated cheese to which additives such as bile salts, flavors, and enzymes are added. Maturation proceeds at relatively high temperatures and high water content in a short time. Lipases and proteases of microbial origin are preferably used.

5.1.4.2.7. Lipase

Milk fat consists mainly of triglycerides. Lipases (triacylglycerol acylhydrolase, E.C. 3.1.1.2) hydrolyze triacylglycerols to di- and mono-acylglycerols, free fatty acids, and glycerol.

Lipolysis plays a significant role in the flavor formation of mold-ripened cheeses, blue cheeses, and some Italian types [540]. In other types of cheese the contribution of lypolysis to flavor formation is still obscure. Milk contains the endogenous lipoprotein lipase (LPL, E.C. 3.1.1.34). This LPL is associated with casein, is consequently incorporated in the curd, and may partially survive pasteurization. In milk this lipase is relatively inactive due to its immobilization on the casein micelle and due to the milk fat being present in milk fat globules surrounded by a protective proteinaceous membrane. Severe agitation or homogenization may damage these structures, after which lypolysis may occur, and the milk becomes rancid.

Pregastric esterases are present in rennet paste and are held responsible for the “piccante” taste of several Italian hard cheeses. Pregastric lipase powders are now used in Italian types of cheese along with a milk coagulant in view of the poor microbiological quality of rennet pastes. Due to pasteurization of raw milk, endogenous lipases are inactivated. Cheese types that, in the past, were made from raw milk are now made from pasteurized milk and added lipases.

Replacement of mammalian lipases by microbial ones is a topic of interest. Lipases from *R. miehei* and Aspergilli strains are commercially available and useful for the manufacture of Italian cheese types. These

enzymes have a preference for hydrolyzing fatty acids located at the 1,3-positions of the glycerol group. The short-chain fatty acids are flavorful and volatile and contribute most to lypolitic flavor development.

Lipases in blue cheeses originate from the *P. roqueforti* surface mold.

5.1.4.2.8. Lysozyme
Hen's egg lysozyme (muramidase, E.C. 3.2.1.17) is an enzyme consisting of 129 amino acids, cross-linked by four S —S bridges and able to split β-(1,4) linkages between *N*-acetylmuramic and *N*-acetylglucosamine residues that constitute the cell wall of Gram-positive bacteria. Lysozyme is found in secretory fluids such as human and cow's milk, tears, and cervical mucus. Lysozyme is active in acidic conditions and is able to withstand 100 °C with little loss of activity.

In the cheesemaking industry lysozyme and nitrate are used in the prevention of the defect of “late blowing”, which is caused by gas (carbon dioxide and hydrogen) produced by outgrowing butyric acid bacteria, in particular *Clostridium tyrobutyricum*. At the same time organic volatile acids are formed, which negatively affect the taste and flavor.

Lysozyme does not seem to affect lactic acid bacteria when applied in low concentrations, although successful application has been reported in the use of lysozyme to accelerate St. Paulin cheese ripening through enhanced lysis of lactic acid bacteria [541].

In its lytic action against the *Micrococcus lysodeikticus* substrate the enzyme is inhibited by the presence of NaCl. This inhibition is stronger at higher pH [542]. For this reason lysozyme is most effective in stages before brining and before the salt has reached the interior of the cheese by diffusion. Lysozyme associates strongly with αs-casein and β-casein but not with κ-casein. This strong association is responsible for almost full retention of lysozyme in cheese curd.

Lysozyme has found many other applications [543] in the preservation of food (meat, fruits, vegetables, seafood, and wine).

5.1.4.2.9. Milk Protein Hydrolysates
A relatively new area of applications has developed for protein hydrolysates. The milk derived caseins and whey proteins are one of the important substrates available in nature. Hydrolysis of proteins has major impact on their functionalities. Fragmentation of the protein due to proteolysis strongly affects its physicochemical characteristics such as molecular shape and size, electrochemical properties, and hydrophobicity, and hence solubility, foaming, and emulsifying and gelation properties. Allergenicity is decreased and taste is severely changed, most often to bitterness. All these characteristics are very much controlled and determined by the degree of hydrolysis of the protein, which in turn is determined by the processing conditions and by the type of proteolytic enzymes used. The degree of hydrolysis can vary from less than 10 to more than 40 %.

Endo- and exoproteases with defined specificities may be employed to control the degree of hydrolysis, the concentration of free amino acids, the peptide size distribution, and even to control the taste, whereby the prevention of bitterness is often a challenge.

Numerous proteases from animal (e.g., pancreatic pepsin, trypsin) or plant (papain, bromealin) origin, but also industrial enzymes from microbial sources (*B. subtilis*, *B. licheniformis*) are used. Aminopeptidases of microbial origin are often used to improve taste, by removing hydrophobic residues from bitter peptides.

Milk protein hydrolysates are used in health and fortifying sports drinks, in infant and low-digestible enteral nutrition, and dietetic foods.

5.1.4.2.10. Transglutaminase
An enzyme which is e to play an important role in the texture and rheological properties of dairy food is transglutaminase (E.C. 2.3.2.13). This enzyme catalyzes the acyl transfer reaction between the Ψ-carboxyamide group of glutamine residues and ε-amino groups of lysine between proteins. In this way high-molecular proteinaceous polymers are built and influence the hydration, gelation, emulsification, and foaming properties of food substrates such as whey protein, casein, soy, and fish meat proteins. The degree

of cross-linking depends on the three-dimensional structure of the protein substrates. The nonglobular structure of caseins or denatured proteins facilitates this cross-linking [544].

In the dairy, applications in the manufacturing of yogurt, preventing syneresis, and in the renneting ability of skim milk in fresh cheesemaking and in cream whipping have been described [545]

5.1.4.3. Milk Processing

5.1.4.3.1. β-Galactosidase

β-Galactosidase (E.C. 3.2.1.23) or lactase is an enzyme that has found ample application in the hydrolysis of lactose, a disaccharide consisting of a glucose and a galactose moiety, in cow's milk. The consumption of milk is hampered for some people due to a deficiency of lactase in the digestive system. Lactose intolerance in these people, predominantly in Asian countries but also in Africa and South and Middle America, results in symptoms such as bloating, diarrhea, and flatulence [546]. In many cases these symptoms occur after consumption of 200 –300 mL of milk.

Hydrolysis of lactose initially results in cleavage next to a glucose molecule, which is released, and an enzyme/galactose complex is formed. Cystein and histidine play an essential role in the active center. The SH group donates a proton to the galactose oxygen atom, and the nucleopholic imidazole group of histidine attacks the C-1 carbon atom of galactose. In the next phase an acceptor ROH (e.g., water) protonates the sulfhydryl anion and liberates free galactose. When the acceptor is another sugar a di-, tri-, or even a polysacharide is synthesized. This activity, also called transferase activity, is made use of in the production of nondigestible oligosacharides. Transferase activity may vary between types of different sources, and oligosaccharide yield is affected by equilibrium concentrations of reactants and reaction conditions.

Ions such as Ca^{2+} and Na^{+} may inhibit the reactions, whereas K^{+}, Mg^{2+}, and Mn^{2+} are activators. The reaction is product-inhibited. Especially galactose strongly inhibits the enzyme-catalyzed reaction.

Table 15 lists microbial sources and characteristics of β-galactosidases [547].

Table 15. Microbial sources and characteristics of β-galactosidases

Origin	$pH_{opt.}$	T_{opt}	K_m (mM) lactose*	*M*, kDa	Activator Inhibitor
Fungal					
Aspergillus niger	3.5	58	85	124	
Aspergillus oryzae	5.0	55	50	90	
Yeast					
Kluyveromyces lactis	6.5	37	35	115	K^{+}, Mg^{2+} Ca^{2+}, Na^{2+}, Zn, Cu
Bacterial					
E. coli	7.2	40	2	540	Na^{+}, K^{+}
B. subtilis	6.5	50	700		
B. stearothermophilus	6.2	55	2	220	Mg^{2+}
L. thermophilus	6.2	55	6	540	

The specific applications of lactases are determined by the optimum pH and pH-dependent stability characteristics of the different lactases. Neutral lactase is predominantly used in the production of low-lactose sterilized milk. Another concept includes lactase tablets to be added to the milk by the consumer a

prescribed period of time before consumption. Acid lactase is able to withstand the acid environment of the stomach and can be consumed with the milk and help the consumer hydrolyze lactose in the digestive tract.

Neutral lactase has also found application in lactose conversion in sweet whey (pH 6.1) and in the manufacture of lactose-free pet milk. Fungal lactase is more suitable in acid whey. Minor applications [547] are found in the manufacturing of yogurt (different outgrowth of cultures), in the sweetening of dairy-based beverages (lactose is less sweet than glucose and galactose), and in preventing the perception of sandiness due to crystallized lactose in ice cream.

5.1.4.3.2. Other Enzymes
Other enzymes such as glucose oxidase (E.C. 1.1.3.4), catalase (E.C. 1.11.1.6), superoxide dismutase, lactoperoxidase (E.C. 1.11.1.7), and sulfydryl oxidase have limited applications. Glucose oxidase, catalase, and lactoperoxidase are involved in the preservation of raw milk. Sulfhydryl oxidase is used to eliminate off-flavors generated due to the UHT treatment of sterilized milk.

5.1.5. Other Food Applications
5.1.5.1. Introduction
The use of enzymes for food applications has increased steadily over the past two decades, not only in traditional application areas such as starch processing, brewing, fruit processing, and dairies. In applications such as baking, the use of enzymes has grown even more [548].

The appearance of new enzyme applications is due to the increasing diversity of the enzymes available, the majority based on GM technology. In future new enzymes for food applications are expected to lead to major developments in the use of industrially produced enzymes [549].

5.1.5.2. Meat and Fish
5.1.5.2.1. Meat Processing
Cooked meat is considered tender if it is easy to chew and, at the same time, retains the desired texture. Tenderness is influenced by a number of factors, which are as yet not well understood. This applies not only to the biochemical reactions involved in rigor mortis, but also to their termination. Indeed, numerous endogenous enzymes take part in this process, including endogenous proteinases, particularly the cathepsins. These enzymes change muscle protein during maturation or aging of meat.

The mechanism of the maturation process has been studied in detail [550]. Natural maturing of carcasses or pieces of meat takes approximately 10 d at 1 – 2 °C. Slow maturation has the advantage of producing very tender meat, but also the disadvantage of moisture loss and shrinkage. Optimal meat maturation in special cold-storage depots (1 – 2°C, 83 – 86 % humidity) leads to a water loss of up to 7 % over three to four weeks. Since 1940, attempts have been made to use exogenous enzyme preparations as meat tenderizers. Proteinases capable of digesting connective tissue and muscle protein have been chosen for this purpose.

Papain (E.C. 3.4.22.2) [9001-73-4], bromelain (E.C. 3.4.22.33) [9001-00-7], and fiacin (E.C. 3.4.22.3) [9001-33-6] are the enzymes used on a commercial scale. The main problem associated with the use of enzymes is their even distribution in the tissue. Factors influencing this distribution are diffusion, time, salt content, and enzyme concentration.

If enzyme preparations are only sprinkled onto the surface of meat (as recommended for kitchen use) or if pieces of meat are dipped into an enzyme solution, only the surface is tenderized, and the interior remains tough. After enzyme application in the kitchen, e.g., using 2 % NaCl with 0.002 % bromelain, the meat is repeatedly poked to make it easier for the enzyme to penetrate. The main effect of the proteinase, though, is exerted during cooking.

Commercial methods can be divided into premortem and postmortem procedures. In postmortem treatment, a proteinase solution is spread in the carcass by repeated injections, possibly under pressure. In the premortem method (the Swift technique developed in 1960) a very pure, sterilized papain solution is injected intravenously 2 – 10 min. before the animal is slaughtered.

Yet another method involves injecting a papain solution that has been reversibly inactivated by oxidation. In the last stages of cooking the enzyme is reactivated by the liberation of mercapto groups.

Pancreatic proteinases are used in the maturation of fish. Bacterial proteinase is employed to dissolve bone meat or segments of meat.

5.1.5.2.2. Fish Processing
Until recently, industrial enzymes have only been used in limited amounts in the fish industry [551]. Today interest in controlling or aiding traditional fish processes has increased, and uses have emerged for enzymes in deskinning, membrane removal, and roe purification.

Fish sauce is a traditional product in some Asian countries, with an annual production of about 250 000 t. The production procedure consists of mixing small, uneviscerated fish with high concentrations of salt and storing the mixture in sealed vessels at ambient temperature for 6 – 18 months. During this process hydrolytic enzymes slowly degrade the fish tissue by proteolytic action with the formation of peptides and amino acids. There is some interest in accelerating fish sauce processing. Plant enzymes such as bromalein, fiacin, and papain digest fish tissue over a shorter period [552], and fungal proteinase increases the initial rate of protein hydrolysis.

Enzyme processes are also important in the traditional *salt curing* of herring, proteolytic enzymes having a favorable effect on both the flavor and texture of salted herring.

Another application of proteolytic enzymes is the *deskinning* of fish such as tuna, which are difficult to skin by manual or mechanical means. This process is based on placing the fish in a warm water bath containing a proteolytic enzyme for 10 – 90 min. After immersion, water jets can remove most of the skin. Enzymes are also used for deskinning and tenderizing squid.

Another use of proteolytic enzymes is in *fish roe purification*. Here the enzyme hydrolyzes the supportive and connective tissue that covers salmon or trout roe eggs and the roe sack, leading to a yield of 85 % compared to 50 – 65 % when using conventional processing. In Scandinavia and Canada 40 – 50 t of caviar (1986) are produced by this method.

5.1.5.3. Protein Cross-linking
The quality of meat protein is an important factor for meat texture and water binding. The addition of ingredients such as vegetable proteins to meat products is well known to improve water binding and other characteristics. It is, however, also possible to improve the meat product by modifying the meat protein by cross-linking. One such modification uses the protein-cross-linking enzyme transglutaminase, which in nature is known to cross-link proteins. The physiological function of transglutaminase cross-linking is to enhance the strength of the molecular structure of the protein network [553]. Substrate specificity is a key aspect in developing protein–protein cross-linking.

Transglutaminase (E.C. 2.3.2.13) catalyzes acyl-transfer reactions, introducing covalent cross-links between proteins, as well as peptides and primary amines. In protein cross-linking, ε-amino groups of lysine residues and ϒ-carboxyamide groups of glutamine residues act as acyl acceptors and acyl donors, respectively (Fig. 45).

Figure 45. Quality relation between bitterness and DH of proteins

Source: Novo, Enzyme Information. IB-number 282-IB. Date 1982-12-23.
[Full View]

Transglutaminase of microbial origin is now commercially available [558] and has found several applications in the meat industry, both as a gelling agent and in connection with improving water binding.

Transglutaminase can also produce restructured meat by binding meat pieces [559], [560]. The meat binding system is based on the use of transglutaminase and caseinate simultaneously. Caseinate treated with transglutaminase acts as a glue to hold food components together. Using this system, a larger piece of

restructured meat or fish fillet can be prepared from smaller pieces. Minced meat can also be bound together without salt and phosphates to give more consumer acceptable products.

5.1.5.4. Flavor Development

5.1.5.4.1. Protein Hydrolysis

Hydrolyzed protein has been used for centuries to improve the taste of food products. The use of soy protein is well known in the production of the soy sauce by enzymatic hydrolysis during microbial fermentation. Soy and other vegetable proteins can also be used to produce a flavoring called HVP (hydrolyzed vegetable protein) by chemical hydrolysis. This chemical hydrolysis, however, has a number of disadvantages, including very high salt concentration and formation of unacceptable components. More recent developments have shown that better results can be obtained by using enzymatic reactions to produce HVP and other flavor-enhancing proteins.

There are many applications for enzyme-enhanced flavors, including soy and wheat hydrolysates for flavoring soups and sauces, and meat hydrolysates for flavor improvement of meat products, soups, and sauces. Milk protein hydrolysis and lipid hydrolysis contribute to flavor improvement in cheese products.

Naturally occurring food proteins do not contribute chemically to flavor formation in foods. It is, however, well known that peptides and amino acids, which are hydrolyzed protein products, do have a flavor. Amino acids taste either bitter or sweet, with the exception of aspartic and glutamic acid which have a sour taste [554]. Traditionally, these hydrolyzed products, available as flavor enhancers for soups and stock cubes etc., have been produced by acid hydrolysis of proteins during heat treatment. Flavors produced in this way are widely used in the food industry. Increasing concern about the less healthy compounds that develop during acid hydrolysis has led to alternative flavor production processes based on enzymatic hydrolysis of protein.

Protein hydrolysates produced by enzymes often have a bitter taste. This bitterness may be more or less pronounced depending on the type of amino acid and the length of the peptides. The development of bitterness depends on the degree of protein hydrolysis. As the degree of hydrolysis (DH) increases, the level of bitterness rises to a maximum before falling again (Fig. 46) [555].

Figure 46. Reaction catalyzed by Transglutaminase (a) Acyl-transfer reaction (b) Cross-linking reaction (c) Deamidation

Source: Ajinomoto information http://www.transglutaminase.com/english/frame/ajinomoto1.htm [Full View]

Bitter peptides are characterised by their high content of hydrophobic amino acids, peptides with a high content of hydrophilic amino acids generally having a bland taste. From present knowledge of the amino acids in common food proteins, it can be predicted that casein-, maize-, and hemoglobin-derived hydrolysates have a tendency to be more bitter, while protein hydrolysates from meat, fish, and gelatin are less bitter.

Flavors produced by enzymatic hydrolyses of protein depend on the type of protein used (animal or vegetable), the type of enzyme, and the combination of enzymes used. By selecting special enzymes, the formation of bitter peptides can to a certain extent be avoided [556].

The ability of protease to develop flavor is used to accelerate the ripening of fermented sausages [557]. The ripening time can be reduced by 30 – 50 % using a combination of endo- and exoproteases (Table 16). The use of proteases in fermented sausages also has an impact on the microorganism used in the fermentation process.

Table 16. Proteases used to accelerate ripening of dry fermented sausages [557]

Enzyme	Type	Source
NCCDO151 proteinase	Serine-proteinase	*Lactobacillus paracasei* subsp. *paracasei*
Pronase E	Mixture of proteinases, amino-and carboxypeptidase	*Streptomyces griseus*
Aspartyl-proteinase	Acid proteinase	*Aspergillus oryzae*
Papain	Thiol-proteinase	*Carica papaya*
Alcalase	Serine-proteinase	*Bacillus lichiniformis*
Bromelain	Endoprotease	*Ananas comosus*
Neutrase	Metalloproteinase	*Bacillus subtilis*
Fungal Protease (Protease P)	Mixture of acid, neutral and alkaline proteinase	*Aspergillus oryzae*
Flavozyme	Mixture of proteases with both exo- and endopeptidase	*Aspergillus oryzae*

5.1.5.4.2. Lipid Hydrolysis

Traditionally, lipase has been used to enhance the flavor of cheese, especially in strongly-flavored products such as Parmesan [557]. Lipase degrades triglycerides and liberates fatty acids, which are generally not flavors themselves (with the exception of short chain fatty acids) but precursors for flavor substances.

Lipases from different sources (Table 17) have been used to enhance flavor development in cheese and dry-fermented sausages.

Table 17. Lipase for flavour development [557]

Enzyme	Type	Source
Lipase	–	Throat glands of kid goat
Lipid esterase	–	*Rhizopus arrhizus*
Lipase	1,3-specific	*Lactobacillus plantarum* MF 32
Pancreas lipase	1,3-specific	Porcine pancreas
Lipase	–	*Mucor miehei*
Lipase	–	*Candida cylindracea*
Palatase M®	1,3-specific	*Rhizomucor meihei*
Lipozyme®	1,3-specific	*Rhizomucor meihei*
Lipase AP6®	1,3-specific	*Aspergillus* spp.
Novozym® 667BG	1,3-specific	*Thermomyces lanuginosus*

Lipases show specificity for fatty acid chain length and esterification position, but it is not completely clear which fatty acid profile is ideal for the flavor profile.

Animal lipases release mainly short-chain fatty acids, whereas microbial lipases release long chain fatty acids. The unsaturated fatty acids released by lipase act as substrates for oxidation reactions and are thus precursors for flavor compounds such as aldehydes and ketones.

5.1.5.5. Egg powder

Egg powder has been produced since the early 1900s. One of the problems faced in connection with egg powder production is the Maillard reaction of protein and glucose in eggs. As early as the 1950s, an enzymatic process was developed to remove glucose from liquid whole egg or egg white (albumin) based on the use of glucose oxidase (E.C. 1.1.3.4) and catalase (E.C.1.11.1.6) [561]. The desugaring of egg albumin with catalase and glucose oxidase is performed at approx. 10 °C, and the pH is adjusted to 6.8 – 7.0 to optimize the performance of the enzymes. This pH adjustment is carried out by slowly adding citric acid solution (to prevent local protein precipitation). Acidification is followed by the addition of hydrogen peroxide. The addition of catalase converts H_2O_2 to oxygen and water (Fig. 47). Glucose is oxidized to glucone δ-lactone by glucose oxidase with oxygen consumption.

Figure 47. Oxidation of glucose by glucose oxidase. Reduction of hydrogen peroxide by catalase. [Full View]

If oxygen becomes the limiting factor, more hydrogen peroxide should be added until the desired glucose concentration (0.1 %) is reached. The desugaring procedure for whole egg or egg yolk is similar to the procedure for albumin, but no acid is added to adjust the pH.

Lipase and phospholipase have recently found applications in egg processing. Egg yolk contains phosphatidylcholine (PC), an emulsifier commonly known as egg lecithin. The enzyme-modified product is derived from the catalytic hydrolysis of a free fatty acid from the PC molecule, which yields lysophosphatidylcholine (Fig. 48). This structural modification improves the emulsification properties of the yolk without altering appearance or nutritional profile. Compared to traditional egg yolk, the structure of emulsions prepared with the enzyme-modified product is more stable and heat-resistant. Generally, the emulsions have greater viscosity and body and are able to emulsify more oil, often at reduced usage levels.

Figure 48. Hydrolysis of Phospholipid by a Phospholipase A2
[Full View]

5.1.5.6. Oils and Fats

The commercial application of enzymes in oil and fat processing is still rather limited. This situation is expected to change over the next few years due to growing interest in milder processes and the availability of new enzymes.

Lipases are by far the most widely used enzymes in oil processing. Their natural ability to hydrolyze oils and fats can be used to enrich oil and fat products with a specific fatty acid. Lipases can also be used to rearrange fatty acids and produce fats and oils with other physical characteristics.

Phospholipase (E.C. 3.1.1.4) is commercially used for removing phospholipids during oil refining (degumming).

Lipoxygenase (E.C. 1.13.11.12) can catalyze the oxidation of polyunsaturated fatty acid.

5.1.5.6.1. Fat Splitting

The hydrolysis of fats and oils is of major importance to the oleochemical industry in the production of fatty acids and their derivatives. These products are used in soaps, detergents, and pharmaceuticals as well as in food applications. Hydrolysis or fat splitting is normally carried out under pressure at a high temperature (typically 3 – 6 MPa and 250 °C). However, this process is not suitable for oils with a high content of polyunsaturated fatty acids. For this type of oil, hydrolysis by an enzymatic process is of great advantage. The enzymatic process is easily carried out at 40 °C in a 50 – 70 % oil-in-water emulsion. To enable reuse of

the enzyme, a number of processes based on immobilized lipase have been developed, making the process more economically feasible.

This principle is of special interest in the enrichment of long-chain polyunsaturated fatty acids from fish oil. Enzymatic hydrolysis of fish oil leads to partial glycerides high in eicosapentaoenic acid (EPA) and docosahexaenoic acid (DHA). *Candida rugosa* lipase is of special interest in this process, because this enzyme shows relatively low activity on DHA compared to EPA [562], [563]. If required, the partial glyceride high in DHA fatty acids can be re-esterified with DHA or EPA to generate triglycerides enriched with these fatty acids (Fig. 49) [564].

Figure 49. Reaction scheme for the enrichment of fish oil

[Full View]

5.1.5.6.2. Interesterification

It is well-known that polyunsaturated fatty acids (PUFA) play an essential role in human nutrition and have important biomedical properties. Therefore, many physical methods have been developed for extracting and enriching these fatty acids, including crystallization, distillation, and the use of supercritical carbon dioxide. Lipase now offers an alternative, having the advantage of mild processing conditions that minimize fatty acid degradation and oxidation. These reactions rely on the principle that some lipases are able to discriminate between certain fatty acids, and that other lipases are selective for the position of the fatty acid in triglyceride moiety.

A special feature of lipases is their ability to work in nonaqueous environments. This property has been used to develop lipase-catalyzed rearrangement processes to generate tailored triglycerides that would be difficult to obtain by conventional physical and chemical methods. Lipases in nonaqueous media utilise the “reverse” reactions, whereby lipases catalyze esterification and rearrangement reactions under low-water conditions (Fig. 50).

Figure 50. Lipase catalysed transesterification reactions

Source: R. Rastall (ed.): Ingredients Handbook, Enzymes, Leatherhead Food International, Surrey 1999.
[Full View]

These systems, however, must contain small amounts of water to keep the enzyme hydrated. Lipases from different sources differ considerably in their ability to work under low-water conditions. Lipase from *Rhizomucor miehei* displays good activity in low water environments ($a_w < 0.2$) and is often used for these types of applications.

Lipase is normally immobilized for this type of reaction. Immobilization presents opportunities for reusing the enzyme, easy separation of the product from the enzyme, and running a continuous process.

The current main application of immobilized lipase in nonaqueous media is the production of tailored triglycerides for use in confectionery fat and nutritional supplements (Fig. 51).

Figure 51. Reactions catalysed by a 1-,3-specific lipase

Source: R. Rastall (ed.): Ingredients Handbook, Enzymes, Leatherhead Food International, Survey 1999.
[Full View]

In the production of cocoa butter substitute (Fig. 52), a mixture of high-oleate sunflower oil (OOO) and stearic acid is passed through a packed bed reactor with immobilised *R. miehei* lipase. The fatty acid exchange occurs in the sn-1 and sn-3 positions of the triglyceride to generate SOS, which is a cocoa butter equivalent. The mixed fatty acid (oleic and stearic acid) is removed and can be hydrogenated and reused. Unwanted triglycerides can be removed by crystallisation and recycled.

Figure 52. Schematic production of cocoa butter equivalent (CBE)

Source: R. Rastall (ed.): *Ingredients Handbook, Enzymes*, Leatherhead Food International, Surrey 1999.
[Full View]

Lipase-catalysed interesterification can also be used to improve the nutritional properties of dietary fat. An example of this is the production of tailored triglyceride for use as a nutritional supplement in infant formula [566]. Human milk fat contains a high proportion of unsaturated fatty acids at the sn-1 and sn-3 positions, with palmitic acid in the sn-2 position. Lipase from the human pancreas releases the fatty acid in the sn-1 and sn-3 positions and produces 2-monoacylglycerol. The body readily absorbs these components.

Human milk substitute based on vegetable oils mainly has saturated fatty acid in the sn-1 and sn-3 positions, which, when released by pancreatic lipase, tends to form calcium soaps and is poorly absorbed by the body. Enzymatic interesterification makes it possible to produce a triglyceride with unsaturated fatty acid in the sn-1 and sn-3 positions and palmitic acid in the sn-2 position (OPO). In this process, palm oil high in palmitic acid is treated with oleic acid to form OPO triglyceride.

Similar techniques can be used to incorporate medium-chain fatty acids ($C_8 – C_{10}$) in specific positions in a triglyceride to generate lipids with improved nutritional properties.

Enzymatic interesterification of fats and oils for margarine and shortening has now become an attractive alternative to the traditional interesterification reaction using high temperature and inorganic catalyst. The enzymatic process is more attractive because it is carried out at 40 – 70 °C, a temperature range in which no *trans* fatty acids are formed.

5.1.5.6.3. Esterification
Enzymatic esterification for the production of diglyceride has attracted interest due to the nutritional aspects of 1,3-diglycerides. Commercial products containing high levels of diglyceride are on the market in Japan, where they have increased their share of the cooking oil market. Use of 1,3-diglyceride in cooking oil contributes to a lower serum lipid level, as pancreatic lipase hydrolyzes 1,3-diglyceride into free fatty acids and glycerol, while no 2-monoglyceride (a building block for serum lipid) is formed.

5.1.5.6.4. Oil Degumming
Crude vegetable oil such as soy oil contains phospholipids, which are normally removed by chemical and physical methods. During the last decade there has been a tendency to move away from chemical (caustic) refining processes and use only physical processes to reduce the amount of effluent. For reliable physical processing, it is essential that the phospholipid content of vegetable oil is reduced to a very low level (< 15 ppm P) before bleaching and deodorization take place.

Crude vegetable oil has a phospholipid content of up to 3 %, depending on the type of seed and extraction

procedure. The first stage of the refining process, water degumming, removes most of these phospholipids, but about 0.6 % nonhydrating phospholipid still remains in the oil. A number of physical methods have been developed to lower the phospholipid content further.

A newer method based on enzymatic hydrolysis of phospholipids by phospholipase A2 has, however, provided an interesting alternative. Phospholipase A2 catalyzes the hydrolysis of fatty acids in the sn-2 position and forms the more water-soluble lysophospholipid, which is more easily washed out of the vegetable oil [567]. This method gives an oil with a residual phosphorus content of less than 10 ppm.

Phospholipase A2 is also used for the production of lysolecithin, which has superior emulsification properties [565]. Lysolecithin is used in the food, cosmetic and pharmaceutical industry.

5.2. Enzymes in Nonfood Applications

5.2.1. Enzymes in Household Detergents

Household detergents need to remove a broad range of complex soil from different fiber surfaces. Soil and stain components with good water solubility are easily removed during the cleaning process. Most other stains are partially removed by the surfactant/builder/bleach system of a detergent, although the result is often unsatisfactory, depending on the washing conditions.

In most cases a suitable detergent enzyme aids the removal of soils and stains. Whereas the detergent components have a purely physicochemical action, enzymes act by degrading the dirt into smaller and more soluble fragments. However, to remove a stain totally still requires the joint action of the enzyme, the surfactant system, and mechanical agitation.

5.2.1.1. Historical Development

The first enzyme-containing detergent was introduced to the household market as early as 1913 when Röhm & Haas in Germany added the protease trypsin, extracted from pig pancreas, to their detergent Burnus, utilizing a patent of OTTO RÖHM [568].

Because the activity and stability of trypsin are moderate in the presence of typical detergent ingredients, the detergent enzyme concept did not really catch on until 1963, when Novo developed and marketed a much more alkali- and builder-tolerant bacterial protease called Alcalase [569].

Small detergent producers in Switzerland (BIO-40 from Gebrueder Schnyder) and the Netherlands (Biotex from Korman and Schulte) were the pioneers in the commercial utilization of Alcalase, which initially was only considered useful for washing bloodstained laundry from hospitals and slaughterhouses.

Gist-Brocades followed a few years later with the alkaline Maxatase protease (1965).

Within five years of their introduction into detergents, more than 50 % of all heavy-duty laundry detergent for domestic use in Europe contained protease enzymes, compared to only 15 % in the USA.

1970 – 1980. The rapid growth of the enzyme-containing detergents was temporarily discontinued in the early 1970s when industrial hygiene and safety problems became evident. Significant improvements in detergent manufacturing techniques, the development of low-dust encapsulated enzyme prills, and improvements in industrial hygiene practices and procedures resolved the issue. Since then enzyme sales have again increased steadily.

The first α-amylase for detergents (Termamyl, from Novozymes) was developed in the early 1970s and has increased tolerance to temperature and alkali.

In the mid-1970s the first liquid detergents were introduced in Europe and the USA using specially developed liquid enzyme preparations.

1980 – 1990. Washing conditions, especially in Europe, gradually shifted further to lower temperatures (from 60 to 40 °C), reduced water quantities, and shorter washing times, and major changes in formulation took place (phosphate-free detergent, activated bleach). New proteases better adapted to these working conditions and new enzyme activities became available.

The first detergent cellulase Celluzyme (Novozymes), a multicomponent cellulase, was developed for improved cleaning and stain removal.

New genetic technology and protein engineering techniques have been introduced for designing further optimized enzymes for detergent conditions or to achieve acceptable production economy. In this way the first bleach-compatible protease (Maxapem, Genencor) and the first detergent lipase (Lipolase, Novozymes) have been developed.

1990 – 2000. New detergent markets opened up in India, South America, Eastern Europe, the former Soviet Union, and China. Because of the specific washing conditions in these regions, such as cost constraints, low detergent concentrations, very low washing temperatures, and presoaking, new enzyme developments were again needed to cope with these difficult washing conditions.

Second-generation detergent proteases, amylases, and lipases were developed by using protein engineering and genetic techniques for further improved performance under difficult washing conditions (low temperature, single wash effects (cleaning, stain removal, whitening, softening, other, achieved with one single wash treatment.)) and with improved compatibility with new detergent technology (improved activated bleach) and for broader application (e.g., in automatic dish washing, liquid detergents, tablets, gel pads).

Up to the 1980s enzymes were primarily developed and used for aiding stain removal and cleaning of fabrics. Since the mid-1990s also enzymes with specific fabric-care effects (color brightening and fabric softening) appeared on the market. (Carezyme and Endolase monocomponent cellulases from Novozymes) as well as enzymes delivering new benefits for stain removal and cleaning (Mannaway, Novozymes).

5.2.1.2. Laundry Soils

Laundry detergents need to remove a broad range of complex soil from different fabrics and fiber types under varying washing conditions. The most frequent soiling on garments and fabrics include all kind of body soils on shirts, underwear, and socks; a variety of food and beverage stains; oily soils; and particulate stains.

The body soils are complex mixtures secreted by sebaceous and sweat glands in the skin or can stem from

fecal, urinal, or vaginal secretions. These soils are mixtures of lipids, proteins, glycoproteins, blood and blood degradation components, skin epidermal debris, salts, and particulate materials collected from the environment. The fresh lipid fraction contains polyunsaturated fatty acids (linoleic and linolenic acid) and their triglycerides and unsaturated hydrocarbons (squalene), which can be rapidly autoxidized when exposed to air, heat, and moisture. The lipid autoxidation reactions yield high molecular mass complex compounds with lipids, proteins, and carbohydrates. This results in a gluelike matter that entraps skin debris and particulate soil components. This aged body soil is tough to remove from fabrics and tends to build up on the fabric during the lifetime of the garment.

The food stains encountered in laundry are also complex soils. They contain substantial amounts of animal and vegetable fats and oils; proteins, e.g., from eggs and meat products; carbohydrates such as sugars, starches, and other complex carbohydrates; residues from plants, e.g., from grass or spinach; and mixed oxidation products. Chemical and enzymatic browning of food products occurs during storage and preparation of foods, mostly by formation of dark-colored Maillard reaction products from carbohydrates and proteins at higher temperatures. Natural dyes and pigments present in foodstuffs such as carotenes and chlorophylls add to the deep coloring of some food stains. In particular carotenes are highly soluble in oils and fats, e.g., in tomato-based sauces, and this adds to the difficulty of removing these stains from fabrics. Certain dairy-based foodstuffs can contain substantial amounts of less common carbohydrate-based gums for stabilizing and texturizing the food, such as carrageenan, guar, and locust bean gums, and these are often difficult to remove from fabrics by detergents and even by current amylases.

Colored stains from beverages such as wines, vegetable and fruit juices, and tea contain complex mixtures of natural dyes and pigments such as anthocyanine and colored polyphenolic compounds, sugars, and organic acids. These materials can eventually be polymerized to higher molecular mass substances that are more difficult to remove from fabrics and fibers. Coffee can in addition contain substantial amounts of browning products formed during roasting of the coffee beans.

Particulate soiling can consist of insoluble metal carbonates, oxides, silicates (clay), carbon black, dust, and humus collected from the environment, e.g., airborne soot on shirt collars or garden soil on socks.

Organic soils on fabrics also can stem from the laundry process and fabric care treatments such as surfactant and builder residues, fabric softeners, and from ironing aids, e.g., starches.

However, the frequency and type of soiling on garments is also geographically different, owing to different consumer habits. Figure 53 exemplifies the differences in soiling incidences in a typical north and south European country.

Figure 53. Soiling in Germany and Spain: incidence ranking [570]
[Full View]

5.2.1.3. Detergent Composition and Washing Process

5.2.1.3.1. Washing Process

Any washing process is an interplay between the washing equipment used; the materials entering the process, i.e., the detergent components and additives; water quality; the wash load composition; and the washing procedures followed, e.g., time, temperature, agitation. The equipment and wash procedures for laundering in three principal geographical areas are summarized in Table 19.

Table 19. Washing equipment and procedures [571]

	USA/Canada	Japan	Western Europe
Machine type	Top-loaded agitator	Top-loaded impeller	Front-loaded rotating drum
Wash time, min	12	10	20–90
Wash load, kg	2–3	1–1.5	3–5
Main wash water volume, L	35–80	30–45	8–15
Main wash temperature, °C	10–50	10–40	30–90
Water hardness, ppm $CaCO_3$	low (100)	very low (50)	high (250)
Recommend product usage, g regular detergent/L	1–5	1–3	5–10

As can be seen the average laundry conditions can vary significantly across the main geographical areas. Within each region also local washing habits exist such as separate addition of hypochlorite-based bleaches in southern Europe; extended boil washing as in Turkey; and multicycle use of the washing water in Japan.

All of this does not facilitate the formulation of detergent effective in the broad range of usage conditions. Often detergent compositions are adapted to these local washing habits.

Not all detergent components are effective over the whole range of temperatures from 4 °C up to boil wash and over the range of detergent concentrations. Here enzymes can become important detergency boosters especially for washing in the low temperature range and under conditions of low product usage.

5.2.1.3.2. Detergent Compositions
Detergent compositions also vary by geography and from country to country.

The household laundry detergents available to consumers can be roughly divided into five segments according to the physicochemical properties of the wash solutions prepared from the detergents:

- Near neutral pH, low ionic strength detergents are mostly liquid detergents having solution pH from 7.5 to 9. They contain no bleach and only low levels of salts. Dilute and concentrated liquid detergents are marketed. The latter type of liquid detergent contains only small amounts of water (< 10 %).
- Mildly alkaline pH, medium ionic strength detergents are typically compact powder detergents from Japan and regular powder detergents from the USA. Their solution pH is about 9 and they contain no bleach.
- Alkaline pH, high ionic strength detergents with a solution pH from 9.5 to 11, and with an activated bleaching system, e.g., European regular powder detergents, They also contain sodium sulfate as a filler, and builder systems, e.g., sodium triphosphate or zeolites and sodium carbonate. High dosages are used, which give a wash liquor with a high ionic strength.
- Alkaline pH, medium ionic strength detergents with bleach are represented by European compact powder detergents, which have gained a large market share during the early 1990s They are compact as a result of removal of most or all of the sodium sulfate; solution pH is from 9.5 to 11.

The household detergents are mostly delivered as low-dusting powders or granulates or as liquids with low or high viscosity (gels). Laundry bar soaps are still popular in certain countries (South Europe, Latin America).

More recently (2000) detergents in tablet form or as a single-dose pouch containing liquid detergent have been launched with success in Europe and North America by Unilever and P & G [572-574].

Practically all of these laundry detergents contain enzymes, although some specialty flanker brands are free of any enzymes. Some specialty laundry detergents combine fabric-cleaning and fabric-care technologies

delivered during the laundering process without use of additives (two-in-one products).

Examples of laundry detergent compositions are given in Table 20.

Table 20. Examples of laundry detergent composition (in wt %) [575]*

	Liquid	Liquid, concentrated	Granular low-bleach, USA/JP	Granular high bleach, Europe	Granular compact, Europe	Tablet
Surfactants	10–50	10–30	7–22	10–20	10–20	15–25
Builders	0–10	5–15	20–70	20–40	20–45	15–30
Bleaches	0	0	0–5	11–27	13–28	10–25
Enzymes	0–6	0–1	0–1	0.3–0.8	0.5–1.5	0–3
pH of 1 % solution	7.5–9	7.5–9	9.5–11	9.5–11	9.5–11	9.5–11

*Surfactants: linear alkyl benzene sulfonates, alcohol sulfates, alcohol ether sulfate, alcohol ethoxylates, cationic surfactants. Builders: zeolites, sodium carbonate, sodium silicate, sodium citrate, sodium tripolyphosphate (STTP), sodium nitrilotriacetate (NTA), polycarboxylates. Bleaches: sodium perborate, sodium percarbonate, tetraacetylethylenediamine (TAED), nonanoyl benzene sulfonate (NOBS) and others. Additives (not listed): foam regulators, stabilizers, processing aids, optical brighteners, antiredeposition agents, corrosion inhibitors, perfumes, colorants, fillers such as sodium sulfate in powders or water in liquid detergents.

5.2.1.4. Enzyme-Aided Detergency and Soil Removal

Soil and stain components with good water solubility are easily removed during the cleaning process. All other stains are partially removed by the surfactant/builder/bleach system of a detergent, although the result is often unsatisfactory, depending on the washing conditions.

In most cases a suitable detergent enzyme may help the removal of soils and stains. Contrary to the purely physical action of the surfactant system enzymes work by degrading the dirt into smaller and more soluble fragments. However, to remove a stain totally still requires the joint effects of the enzyme, surfactant system, and mechanical agitation.

Proteases and amylases can remove protein and starch stains, respectively. Fats and oils are generally difficult to remove at low wash temperatures (< 40 °C) by conventional detergents. By using lipases, it is possible to improve the removal of fats/oils of animal and vegetable origin even at temperatures at which the fatty material is in a solid form.

Particulate soils can be difficult to remove, especially if the particle size is small. Removal of particulate soil from cotton fabric can be improved by use of a cellulase that removes cellulose fibrils from the surface of the yarn.

Various kinds of dirt may adhere to textile surfaces via a glue of proteinaceous, starchy, or fatty material. In such cases of anchored dirt, an enzyme may assist in removing the dirt even though it does not attack the dirt directly. Compounds from several of these classes are intimately mixed in combined soiling, e.g., human sebum on shirt collars, cocoa milk, gravy, or chocolate.

Bleachable stains are the only group of stains for which no enzyme product for detergent applications has been marketed so far. However, the patent literature indicates that efforts are being made by the major enzyme suppliers and detergent producers to develop an enzymatic bleaching system for detergents.

5.2.1.5. Detergent Enzyme Performance Evaluation and Screening

Not all enzymes with a potential for stain degradation and/or removal are suitable for inclusion in detergent products. Enzyme performance is influenced by factors like detergent solution pH, ionic strength, wash

temperature, washing time, detergent composition, and mechanical handling. Detergent surfactants, bleach systems, and other enzymes can influence both performance and stability.

The enzymes must have a broad enough substrate specificity because the average load of dirty laundry contains the enzyme substrate in a multitude of forms. For example, in the case of proteases the protein substrate may have been oxidatively modified or complexed with carbohydrates.

A detergent enzyme must be active at the pH of detergent solutions (between 7 and 11) and at the relevant wash temperatures (4 to 60 °C). Importantly, the enzyme must be compatible with detergent components such as surfactants, builders, bleaches, and other enzymes, not only during the wash process but also upon storage when incorporated in the detergent. In particular, such an enzyme must be resistant toward denaturing surfactants and bleach and towards protease degradation under these conditions.

Enzymes can be screened by assay of their activity on soluble substrates under conditions different from those encountered in a realistic wash. Enzyme screening often uses spectrophotometric assays with chromophoric soluble substrates, and the procedure can be fully automated for high-throughput analysis. The assay results can indicate the enzyme's performance on soluble substrates with respect to pH and temperature variations and with respect to enzyme compatibility with detergent components or enzyme-inhibiting conditions, etc. However the analytical data thus obtained with soluble substrates are not necessarily representative of the wash performance of the enzyme, and often low correlation is achieved with performance results obtained with enzymes under realistic laundry conditions (Fig. 54).

Figure 54. Example of deviating analytical activity on soluble substrates and laundry scale cleaning performance data [576]. Savinase protease: analytical performance on denatured hemoglobin, 25 °C, 10 min.; wash performance on grass stain, 30 °C, 10 min.
[Full View]

It is also important to realize that enzymes can have significant performance effects on substrates that apparently are unrelated to their target substrates. For example, proteases can deliver significant performance benefits on removal of protein-based bloodstains but also on grass stains on fabrics. Therefore real wash trials using a broad range of consumer relevant stains remain necessary to completely evaluate the wash performance of detergent enzymes.

Wash-performance assessments often use pre-soiled test pieces. For example the commonly used stains for protease evaluation are milk, blood, and grass applied to cotton or synthetic fabrics. These stains also may contain particulate matter, e.g., carbon black, as part of the stain matrix. These standardized test materials are available ready-to-use from a number of research and testing institutes in Europe and the USA, e.g., Center for Test Materials, Vlaardingen, Holland; Wascherei Forschungs Institut, Krefeld, Germany [577]; EMPA St. Gallen, Switzerland [578] (Table 21); Instituut voor Reinigingstechnieken TNO, Delft, Holland [579]; Test Fabrics, Middlesex, New Jersey [580] and SDL Textile Innovators [581]. Alternatively, enzyme manufacturers can supply stain preparation procedures, or specific stain material can be made in-house by the enzyme formulator. Finally, naturally soiled and stained fabrics obtained from households can be used for more realistic performance assessment.

Table 21. Examples of standard performance test materials from EMPA [578]

Soil	Cotton fabrics	Polyester/cotton blend
Carbon black/olive oil	101	104
Blood, milk, carbon black	116	117
Lipstick	141	142
Make-up	143	144
Starch	161	162
Tea	167	168
Grass	164	
Blood	111	
Wine (red)	114	

Laboratory wash trials are usually conducted in small-scale models of washing machines. The Terg-o-tometer [582] simulates the top-loaded U.S. type of washing machine, and the Launder-o-meter [583] or Linitest [584] simulates the European drum-type machine [585]. These small-scale models use 0.2 to 1 L of wash solution. Both have temperature-controlled heating and a timer. The wash solution is agitated with an impeller in the Terg-o-tometer and by rotation of a closed pot in the Launder-o-meter or Linitest equipment. The test stain of defined size is laundered in the wash solution with controlled detergent concentration and solution pH and with or without the enzyme under test. The enzyme concentration in the initial screening tests can be in the range of 1 - 100 mg/L of enzyme degradable protein.

The evaluation of the enzyme effects on the test pieces can be made visually by grading by an expert panel under controlled illumination conditions and by instrumentally measuring the reflectance of light under specified conditions. Typically, the intensity of light remitted R at 460 nm when illuminating the test pieces with a standardized daylight source is expressed as a percentage, ΔR or ΔE, of the intensity of incident light at the same wavelength. The ΔR or ΔE value is then a measure of the enzyme effect; it is defined as the difference in R between fabrics washed with and without enzyme. The R value is known to correlate well with the visual impression of whiteness of the fabric. Depending on type and degree of soiling, differences in R or E of 2 – 3 units are detectable by the human eye.

Digital imaging systems can be used for the instrumental evaluation of the performance effects in larger routine performance screening of enzymes using standardized stains and small-scale laboratory performance test methods.

For the complete evaluation of detergency effects of an enzyme two-steps can be considered: (1) “Primary washing effects” (cleaning efficacy) refer to the removal of soil and stains after one wash. Testing is carried out as described above using either artificially soiled test fabrics or naturally soiled laundry. (2) “Secondary washing effects” (effects after repeated washing) refer to potential multiwash performance (e.g., with Lipase) or to the detection of damage such as loss of tear strength, incrustations (ash residues), and graying. The latter evaluations are usually based on 25 or 50 washes, including a control fabric.

A convenient way to report detergent enzyme performance is the use of dose – response curves. Typically, the enzyme-related performance increases significantly in the lower enzyme concentration range, but reaches a maximum level at higher enzyme doses.

Figure 55 compares protease performance as a function of enzyme dosage. The performances at 60 °C reaches a plateau at an enzyme dosage of approximately 0.04 wt % of the enzyme granulate in the detergent. At this enzyme concentration, the fabric is clean and the stain can be totally removed, i.e., the measured R value is identical to that of an unsoiled test piece washed under the same conditions.

Figure 55. Example of a dose response curve for Savinase 6.0 T protease (Novozymes) in a powder detergent, 4 g/L in a Launder-o-meter test at 60 °C for 40 min. Source: Novozymes.
[Full View]

The extent to which the enzyme is able to remove stains and soils from the fabric depends on the detergent composition, the wash temperature, wash solution pH, washing time, wash load, etc. Enzyme wash performance varies between liquid and powder detergents and with the composition of the soiling. Figure 56 shows that the fabric composition also influences the stain-removal profile for the same soiling (EMPA 117 on polyester – cotton and EMPA 116 on cotton only).

Figure 56. Stain removal performance of a U.S. liquid detergent (0.4 % Savinase 16L) and a U.S. powder detergent (0.8 % Savinase 8.0T) on different standard soilings in a Terg-o-tometer operating at 6°dH water hardness, 20 °C, 10 min. EMPA 117 (milk, blood, and ink on polyester/cotton); AS 10 (milk, oil, and pigments on 100 % cotton); grass (on 100 % cotton); EMPA 116 (milk, blood, and ink on 100 % cotton); WFK blood soiling (on 100 % cotton). Source: Novozymes.
[Full View]

Further scale reduction of the performance evaluation of detergent enzymes has been achieved, and high-throughput performance screens for enzymes are being developed. This type of performance assessment uses multiwell titer plates, each holding milliliter volumes of wash solution under controlled temperature conditions (Figure 57). A realistic level of agitation of the solution is assured with miniaturized stirrers. Using optimized test conditions a good correlation with real laundry conditions can be achieved. The performance can be evaluated visually or preferably instrumentally using titer plate readers and software that are commonly used in protein chemistry. Such miniaturized performance assessment has many advantages such as very low consumption of enzyme, on the order of micrograms versus milligrams in other small-scale tests, and the high-speed evaluation of many performance conditions in a multiwell experiment.

Figure 57. High-throughput performance screen for detergent enzymes. Enzyme performance on grass stain is evaluated at one enzyme level versus the hardness profile of the wash solution (0 – 10mmol Ca^{2+}). Left: the multiwell grass stain after treatment; right: instrumental evaluation of the multiwell grass stain. Source: unpublished data courtesy of G. Bechmann, C. Joos, S. Cooremans (Procter and Gamble Eurocor).
[Full View]

The final conclusion on the performance of a detergent enzyme candidate must be confirmed in a realistic laundry appliance using realistic wash loads and with wash programs at various wash temperatures and detergent usage versus water hardness. Finally these performance tests can be repeated in all important geographical or local washing conditions to confirm the robustness of the enzyme to the wash conditions.

5.2.1.6. Enzyme Types

5.2.1.6.1. Proteases

Proteases hydrolyze proteins into smaller fragments, i.e., peptides or amino acids. In a detergent context, protein stains on fabric (laundry) or hard surfaces (e.g., in dishwashing) are degraded into fragments which can be removed or dissolved by other components of the washing liquor.

Proteases are well-established ingredients in most household laundry detergents worldwide, except in some developing countries. They are used to remove stains such as blood and grass. The effects of proteases are very clear, and the enzyme cost, considering the effect, is relatively low. On some food stains, e.g., cocoa, a combined effect with amylases or lipases may be observed.

Most of the commercial detergent proteases are subtilisins and are classified as such in the Chemical Abstract Service. The Enzyme Classification number is E.C. 3.4.21.62. The name subtilisin derives from the name of the bacterial species, *Bacillus subtilis*, from which the protease was first isolated. Subtilisins are extracellular serine endo-peptidases, and the term also now covers proteases isolated from related *Bacillus* species.

The first protease of this type was subtilisin Carlsberg from *Bacillus licheniformis*, isolated in 1947 (also known as subtilisin A, Alcalase Novo). Later, in 1954, subtilisin was also isolated from *B. amyloliquefaciens*, also known as subtilisin BPN′, Nagase, Primase, Bacterial Proteinase Novo, Sub Novo.

The commercial detergent proteases are very similar in structure, and there are no fundamental differences between them. They are all characterized by very broad substrate specificity and mainly differ in temperature optimum, pH optimum, bleach sensitivity, and Ca ion demand. Some are highly alkaline, i.e., have a maximum activity in the high pH range, such as Maxacal and Savinase. Others are low-alkaline, e.g., Maxatase, Alcalase, and Subtilisin Novo (BPN′). Table 22 presents examples of commercially available protease and application ranges. They all have a molecular weight between 20 000 and 30 000, and have a serine residue in the active site of the enzyme. Figures 58 and 59 illustrate the pH and temperature profiles of some commercial low- and high-alkaline protease in analytical assay on dimethylcasein (DMC) substrate

Table 22. Examples of commercially available detergent proteases (Novozymes) [587-591]

Product name	Microorganism	pH application range	Temperature application range
Alcalase	*Bacillus* species	6 – 10	10 – 80
Esperase	*Bacillus* species	7 – 12	10 – 80
Everlase	GM *Bacillus* spp.	8 – 11	15 – 80
Savinase	GM *Bacillus* spp.	8 – 11	15 – 75
Durazym	GM *Bacillus* spp.	8 – 11	15 – 70

Figure 59. Temperature-dependent activity of different detergent proteases in solution at pH 8.5 (Alcalase) and 10.1 (Savinase, Esperase), 10 min reaction time, DMC substrate [588-590].
[Full View]

Protease performance can be strongly influenced by detergent pH and ionic strength. Surfactants influence both protease performance and stability in the wash solution. In general, anionic surfactants are more aggressive than amphoteric surfactants, which in turn are more aggressive than nonionic surfactants.

All detergent proteases are destabilized by linear alkylbenzenesulfonate (LAS) and alkyl sulfates (AS), the most common types of anionic surfactants in detergents. The higher the LAS concentration and wash temperature, the greater the inactivation of the enzyme. The presence of nonionic surfactants or ethoxylated alkyl sulfates, however, counteracts to some extent the negative effect of LAS. Since almost all detergents contain some nonionic surfactant or ethoxylated AS, the stability of proteases in a washing context is not problematic.

Phosphate builders such as sodium triphosphate and non-phosphate builders such as zeolite and citrate remove free calcium from the washing solution. Co-builders such as nitrilotriacetic acid and polycarboxylates also may be incorporated into the detergent formulation. Wash performance of detergents decreases with increasing calcium concentration. Protease performance varies, but high calcium concentrations tend to reduce protease performance. Therefore, it is an advantage to add a builder system to the detergent. Proteases need a small amount of calcium for the sake of stability, but even with the most efficient builder systems, stability during washing is generally not a problem.

Bleach systems in laundry products can also oxidize proteinaceous stains on fabric, often making them more difficult to remove. Detergent proteases can partly counteract this negative effect of the bleach system. Most detergent proteases are stable during the wash cycle in the presence of such oxygen-based bleach systems.

However, storage stability in detergents containing bleach may be a problem with the established detergent proteases. In particular, the amino acid methionine in the protease molecule can be oxidized during storage by the bleach system in powder detergents, which leads to inactivation of the protease. For example the Savinase detergent protease contains methionine residues in three positions, one of which is next to the active site serine. In new protein-engineered proteases introduced onto the market the most bleach-sensitive amino acid, i.e., methionine close to the active site, is replaced with other amino acids insensitive toward oxidation. This slight change in the molecular structure significantly increases the storage stability in detergents containing bleach. Bleach-stable proteases developed by using protein engineering include Everlase (one amino acid change from Savinase) and Purafect OxP, which are superior to Durazym and Purafect with respect to washing performance in bleach-containing detergents. In addition, the bleach-stabilized proteases also usually have better storage stability when formulated in bleach-containing detergents (Fig. 60).

Figure 60. Storage stability of bleach-stable protease (Everlase, Novozymes) in European powder detergent with activated bleach system. Storage at 37 °C, 70 % R.H., open vial [587].
[Full View]

Chlorine bleach (sodium hypochlorite, NaOCI) is not incorporated into laundry detergents themselves, but can be used as a separate additive to the wash, as is common practice in some parts of the world. Hypochlorite bleach in excess of 200 ppm in the normal wash can quickly oxidize enzymes, resulting in significant loss of enzyme activity. Bleach-stabilized proteases can survive low concentrations of NaOCl, as depicted in Figure 61.

Figure 61. Performance activity of a bleach-stable protease (Everlase, Novozymes) versus parent protease (Savinase, Novozymes) in the presence of chlorine bleach. Grass stain removal, Terg-o-tometer, U.S. HDP at 1 g/L, pH 9.3, 40 °C, 10 min, 10° dH waterhardness [587].
[Full View]

5.2.1.6.2. Amylases

Commercial laundry amylases comprise the α-amylase from *Bacillus amyloliquefaciens* and the heat-stable α-amylase from *Bacillus licheniformis* and from *Aspergillus* species.

α-Amylase (E.C. 3.2.2.1) catalyzes the endo-hydrolysis of 1,4-alpha-D-glycosidic linkages in polysaccharides containing three or more 1,4- α-linked glucose units. The enzyme acts on starches, glycogen, and oligosaccharides in a random manner, liberating reducing groups. α-Amylases are characterized by attacking the starch polymer in an endo fashion, randomly cleaving internal α-1,4 bonds to yield shorter, water-soluble dextrins. They are the preferred type of amylase for laundry detergents, and are included in both powder and liquid formulations in many countries. α-Amylases boost overall detergent performance at lower wash temperatures and with milder detergent chemical systems.

Other starch-degrading enzymes of potential interest are β-amylases (E.C. 3.2.1.2) and pullulanase (E.C. 3.2.1.41), but these have not been commercialized on industrial scale for detergent application. β-Amylases differ from α-amylase in that they hydrolyze 1,4- α-D-glycosidic linkages, removing successive maltose units from the nonreducing of the polysaccharide chain. This exo-type activity is not as efficient for stain removal. Pullulanase is a starch-debranching enzyme and hydrolyzes the 1,6- α-D-glycosidic bonds in amylopectin and pullulan, debranching the amylopectin. A mixed amylase and pullulanase enzyme system can accomplish a more complete degradation of starch.

Table 23. lists some application conditions for α-amylases for detergent applications.

Table 23. Commercial amylases (Novozymes) [592], [595], [597], [598]

Product name	Microorganism	pH application range	Temperature application range
Termamyl	GM *Bacillus* species	6 – 11	25 – 100
Duramyl	GM *Bacillus* species	6 – 10	25 – 100
Natalase	GM *Bacillus* species	5 – 10	10 – 60
BAN	*Bacillus* species	5 – 8	15 – 90
Fungamyl	*Aspergillus* species	4 – 7	15 – 60

α-Amylases catalyze the degradation of starch-containing stains, and improve cleaning by hydrolyzing the starchy glue that binds other dirt and stains to fabric. However native starch is only slowly degraded by α-amylases. Gelatinization and swelling are needed to make the starch susceptible to enzymatic breakdown. For most food stains, various degrees of gelatinization result from cooking of starch-containing foodstuffs, e.g., pasta, potato, gravy, and baby food.

If the food processes did not exceed the starch gelatinization temperature, the starch may be in the form of partly or nongelatinized granules, or it may be partly retrograded. Such starch may be amorphous and is usually difficult to remove from surfaces without boil washing. The presence of an amylase renders boil wash superfluous in laundry process and enhances laundry-cleaning performance of detergents at lower wash temperature.

Gelatinized starch may form a film on fabric that can result in an increased pick-up of particulate soil after washing [593]. Starch stains combined with particulate soiling are more difficult to remove than starch alone. As a result white laundry items turn increasingly gray after repeated wash cycles, an effect that has been demonstrated by adding about 0.5 g starch per kilogram of cotton fabric [594]. Starches may react differently depending on their amylose content, which is thought to be the film-forming component of the starch. Film formation is favored under European laundry conditions, in which the temperature may be

closest to the starch gelatinization temperature.

In laundry detergents, amylases may maintain or even contribute to increased whitening of dingy fabrics [593] and inhibit the graying of white fabrics resulting from a combination of starch and particulate soiling, as illustrated in Figure 62. A noticeable amylase effect is obtained with pre-spotting (at high concentration), and with presoaking (prolonged reaction time).

Figure 62. Effects of added starch in solution on particulate soiling and removal with amylase and European granular detergent. Treatments: A) no starch added and washed with amylase-free detergent; B) starch added and washed with amylase-free detergent; C) starch added, washed with 0.4 KNU/L (Kilo Novo Units per Liter) Termamyl and detergent, D) starch added, washed with 1.2 KNU/L Termamyl and detergent [594].
[Full View]

Examples of artificially soiled test pieces used to test the performance of amylases include cocoa/milk/sugar, cocoa/sugar/potato starch, cocoa/milk/sugar/potato starch, and starch/carbon black, all on cotton or polyester/cotton.

Bacterial α-amylases used in laundry detergents are fully compatible with detergent proteases, i.e., the two enzymes work together in the wash process. During storage in both powder and liquid detergents, the amylases are stable in the presence of proteases.

The stability of some calcium-dependent α-amylases can be enhanced by addition of small amounts of calcium salts to the detergent composition.

For bleach-containing detergents, bleach-resistant α-amylases have been developed by using protein engineering and genetic techniques, as indicated above for proteases. Figure 63 illustrates the gain in amylase enzyme stability, as indicated by the improved residual enzyme activity over time in a bleach-containing solution.

Figure 63. Residual activity of bleach-stable α-amylase (Duramyl) compared to standard amylase (Termamyl) in 100 mM hydrogen peroxide at pH 9.0, 40 °C, 0.1 mM Ca^{2+} [597]
[Full View]

Protein-engineering and genetic techniques have been used to develop α-amylase with lowered optimum temperature for enzyme activity, specifically for low-temperature wash conditions with heavy-duty liquid detergents. Figure 64 illustrates the reduced optimum working temperature for such a low-temperature amylase developed by Novozymes. The significantly improved performance of such low-temperature α-amylase in a cold-water wash (25 °C) in a Mexican powder detergent is shown in Figure 65.

Figure 64. Optimum temperature of low-temperature amylase (Natalase) versus standard (Termamyl) amylase [595], [598]

5.2.1.6.3. Lipases

Lipases (E.C. 3.1.1.3) hydrolyze triacylglycerol (triglyceride) substrates, as are present in fats and oils. Because of their strong hydrophobicity, fats and oils are difficult to remove from laundry at low temperatures. A triglyceride molecule is composed of three fatty acid moieties linked to a glycerol backbone by ester bonds. Lipases hydrolyze triglycerides to more hydrophilic mono- and diglycerides, free fatty acids, and glycerol. These hydrolysis products are all soluble under alkaline wash conditions.

Many patents have demonstrated that lipases can improve the removal of fatty stains when used in powder and liquid detergents, special pre-soakers, or other cleaning agents. Intense research activity is also reflected in the literature.

Lipolase was the first commercially available lipase for detergents and the first detergent enzyme produced by genetic engineering to achieve an acceptable production economy. Leading brands in the USA and Europe included lipase from 1990/1991 [599] in powder and in liquid detergents.

The slow development of a commercial detergent lipase was due to low fermentation yields and to difficulties in finding lipases with the appropriate characteristics for application in household detergent products. Patent literature indicates the only feasible way to produce lipases at an acceptable cost/performance ratio is by genetic engineering [600-602]. Lipolase was originally isolated from the fungus *Thermomyces lanuginosus* (formerly *Humicola lanuginosa*) with low levels of enzyme expression. By using rDNA techniques the lipase is expressed in acceptable yields in the harmless host microorganism *Aspergillus oryzae* [598, 603] in the current commercial production process.

Protein engineering and genetic techniques delivered improved lipase enzymes for detergent applications. For example Lipolase Ultra by Novozymes is a protein-engineered variant of Lipolase that has improved washing performance at lower temperatures, i.e., below 20 °C. The change made by protein engineering involves replacing a negatively charged amino acid in the lipid-contact zone of the Lipolase molecule. More precisely, aspartic acid (negatively charged) in position 96 has been replaced with leucine (neutral, hydrophobic). The change reduces the repellent electrostatic forces between the soil and the enzyme, making the active site more hydrophobic so that the affinity to a lipid contact zone on the textile surface was improved.

Another protein-engineered variant of Lipolase is LipoPrime for better first-wash effect, especially under European washing conditions. Further efforts are now being made to develop more “first-wash lipases” [604].

Surface-active molecules such as surfactants and fatty acids/soaps can strongly inhibit lipase enzymes [605]. Because of the presence of free fatty acids in the mix of hydrolysis products, pH strongly influences lipase activity and the removal of decomposed stains. The best rate of removal requires a pH above 8 [606]. Above pH 8 the hydrolysis reaction may be favored by small amounts of free Ca ions due to the formation of Ca soap, although lipases are also effective at low concentrations of free calcium [607]. The more the fatty stain is hydrolyzed by the lipase, the easier it is to remove the stain from the fabric due to its increased hydrophilicity.

However the effects of conventional lipases are seen only after several wash cycles (“multi-cycle wash performance”), as illustrated in Figure 66.

Figure 66. Multi-cycle wash performance of lipase in detergents. Stain removal as function of number of wash cycles. European wash conditions 5 g/L powder detergent, 30 °C, 20 min, wash at pH 9.7. Polyester swatch soiled with lard fat plus Sudan red [610].

LU/L = Lipase Units per Liter
[Full View]

Surprisingly, lipases are also active during a certain period of the drying step [604], [610] during line drying, and in tumble dryers, Lipolase displays maximum activity when the moisture content of the fabric is 20 – 30 wt %. This means that significant decomposition of any residual fatty matter will take place while the laundry is drying. This hydrolytic activity does not result in an immediate advantage in terms of fat removal, but the next time the stained fabric is washed the stain will be removed more effectively. Figure 67 illustrates lipase enzyme activity in the drying step.

Figure 67. Lipase performance in the laundry drying step. Relative enzyme activity during drying after a European wash and one rinse with tap water [612].
[Full View]

Lipases have proven to be effective in pre-spotters and other liquid detergent formulations when used in undiluted form for pretreatment of tough fatty stains. The low water content on the fabric in this situation is believed to be responsible for the high lipase activity and stain-removal performance in these conditions.

In *performance testing* of lipase detergent enzymes, three consecutive washing/drying cycles are usually employed. Washing temperature, time, and Ca^{2+} concentration depend on the geographical area where the detergent is used. After washing and drying, the reflectance of the colored, lard-containing test swatches is measured, and the remaining lard may be extracted for quantitative determination.

The multiple-wash performance effects of a detergent lipase are shown in Figure 66.

Lipase can cause *malodors* on butter- or fat-stained fabrics by releasing short-chain free fatty acids [605]. Lipases also may indirectly create malodor from laundry items such as sweaty sports clothes. The main reason for malodor (at least in the case of sports clothes) is the survival of microflora. The problem is therefore most pronounced in detergents without bleaching agents. Under normal drying conditions, lipases do not give rise to additional malodor, but if the drying takes several days some lipase-associated malodor may develop. In laundry detergents, the dosage of lipase is often limited by the maximum acceptable malodor.

5.2.1.6.4. Cellulases

Cellulases cleave β-1,4-glycosidic bonds in cellulose and operate directly on the natural cotton fibers or cotton/flax blends and on the cellulose portion in blended cotton/synthetic fibers. This enzyme class is divided into endo-cellulases (endo-glucanase, EG; E.C. 3.2.1.4) and exo-cellulases (cellobiohydrolase, CBH; E.C. 3.2.1.91). EG-type cellulases catalyze the endo-hydrolysis of 1,4- β-D-glycosidic linkages in cellulose, lichenin, and cereal β-D-glucans. CBH-type cellulases hydrolyze the 1,4- β-D-glycosidic link in cellulose and cellotetraose, releasing cellobiose from the nonreducing ends of the cellulose chain. For both EG and CBH cellulases, many iso-enzymes with slightly different substrate specificities and optimum working conditions have been identified.

The cellulase enzyme molecule is composed of up to three types of functionally different domains, as illustrated schematically in Figure 68: (1) the catalytically active core, which is a large, spherical domain; (2) the linker domain, which is an elongated and flexible spacer; and (3) a spherical cellulose-binding domain (CBD).

Figure 68. Schematic presentation of a multi-domain cellulase adsorbed to cellulose substrate. The enzyme having a catalytic core, a linker, and a cellulose-binding domain [592].
[Full View]

The nature of the core determines catalytic properties such as endo activity versus exo activity, substrate specificity, and the type of reaction products that are formed. The presence of a CBD is of particular importance for binding of the enzyme on insoluble and crystalline cellulose and for hydrolytic effects. Both EG- and CBH-type cellulases can contain linkers and cellulose-binding domains.

Table 24 lists some application conditions and a few comparative characteristics for some commercially available detergent cellulases from Novozymes. These cellulases can be used in heavy-duty liquid detergents, in bleach-containing powder detergents, and in a number of “color” and compact detergent powders.

Table 24. Examples of commercially available cellulases from Novozymes and application conditions. Source: Novozymes cellulase application sheets

Product name	Microorganisms	Cellulase type(s)	pH range	Temperature range
Celluzyme	*Thermomyces lanuginosus*	CBH 1, CBH II, EG I, EG II, EG III, EG V, and EG VI	4 – 10	25 – 70
Carezyme	*Thermomyces lanuginosus*	EG V	5 – 10.5	25 – 70
Endolase	*Thermomyces lanuginosus*	EG II	5 – 9	25 – 70

As an example the pH and temperature profiles of Carezyme are presented in more detail in Figures 69 and 70.

Figure 69. Temperature-dependent activity of EG V cellulase (Carezyme, Novozymes) at solution pH 8.5 and 100 ECU(CP) [Endo Cellulose Unit (Carezyme Product)] enzyme concentration, 20 min. reaction time [616].
[Full View]

Figure 70. pH-dependent activity of EG V cellulase (Carezyme, Novozymes) at 40 °C and 100 ECU (CP) enzyme concentration, 20 min. reaction time [616].
[Full View]

Cleaning by removal of particulate soils, softening, and improved color brightness are the three basic benefits obtained from cellulases. Cellulases are unique in providing these effects.
